RECENTLY[1] a double mercury discharge vessel was used (Fig. 1), in which a large current running in the outer vessel irradiated the small current discharge in the inner vessel with 2537 Å resonance radiation. This irradiation caused the running voltage and electron temperature in the inner discharge to be reduced appreciably over the non-irradiated mode of operation. The explanation offered was that the neutral Hg atoms in the inner vessel absorbed the resonance radiation and entered the 6^3P_1 state (see Fig. 2), and from this level the atom was ionized by electron impact. In addition the 6^3P_0 and 6^3P_2 metastable levels are populated from the 6^3P_1 level by electron collisions and by cumulative absorption and radiative decay of higher levels. Because the radiation field is doing approximately half the ionization work, the electron temperature drops correspondingly.

The present communication suggests the possibility that such a double discharge could form the basis of an isotope separator, if the outer, irradiating discharge were run in a pure isotope and the hyperfine components of the resonance line are separate. We show in Fig. 3 the hyperfine components of the Hg 2537 Å line and it is seen that ^{200}Hg and ^{202}Hg could be separated by this method. In this situation only the isotope in the inner discharge which corresponds to that in the outer will be excited, and thus the Hg ions which are accelerated to the discharge wall by the radial electric field will be predominantly of one isotope. The details of the collection of ions at the wall are not considered here.

It is interesting to note that this method differs from other methods in current use in that it does not depend directly on

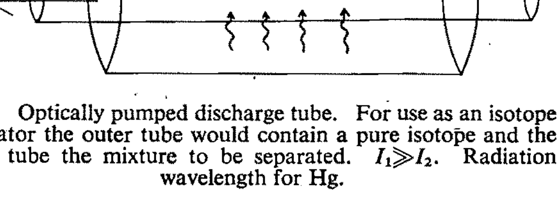

Fig. 1 Optically pumped discharge tube. For use as an isotope separator the outer tube would contain a pure isotope and the inner tube the mixture to be separated. $I_1 \gg I_2$. Radiation wavelength for Hg.

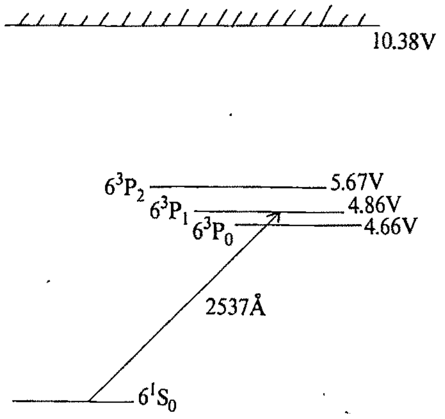

Fig. 2 Simplified Hg energy level diagram.

the isotope mass ratios, which for heavy elements are almost unity.

In the case of Hg isotope separation the inner discharge changes to the radiation-assisted mode only for Hg gas pressures greater than 10 mtorr[1]. At these higher pressures the ion on its way to the wall will suffer charge exchange collisions with Hg atoms of all isotopes and so the ion wall current will not be of the pure isotope. In the case of Hg, further experiments in our laboratory have shown that the addition of a few mtorr[1] of N_2 to the Hg facilitates the transition to the radiation-assisted mode, at only 1 mtorr of Hg, where the charge exchange mean free path for Hg^+–Hg collisions is fairly long. It is believed that this improvement is caused by collisions between Hg 6^3P_1 atoms and N_2 in the $v=0$ vibration state, giving Hg 6^3P_0 and N_2 ($v=1$), (ref. 2), and because the Hg 6^3P_0 metastable state has a much longer lifetime than that of Hg 6^3P_1, the electron impact ionization makes more efficient use of the radiation assistance. If this is the explanation, then CO should be even more efficient an additive than N_2 (ref. 2), because the quenching cross-section of CO for $6^3P_1 \rightarrow 6^3P_0$ is much greater than that of N_2. Such high ionization potential additives as N_2 and CO result in Hg being the predominant ion even up to molecular gas pressures considerably greater than the Hg pressure.

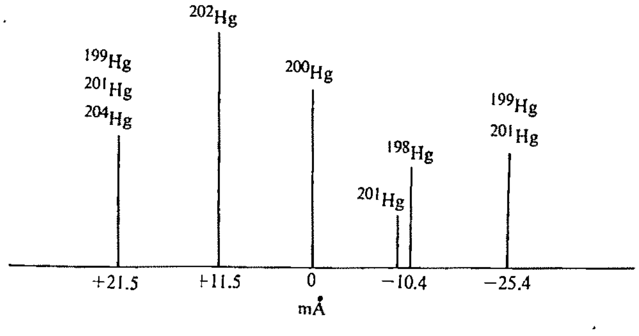

Fig. 3 Hyperfine structure of the 2537 Å resonance line.

Extension of this method to other elements is dependent on the fulfilment of several criteria, among which are that, first, the hyperfine components must not overlap and, second, that the mean free path for radiation absorption be equal to or less than the mean free path for charge exchange.

This latter criterion is probably not satisfied by uranium, although its spectroscopic properties are poorly known[3].

We thank Professor D. W. Holder for support in this work which was carried out under contract from the Culham Laboratory (UKAEA). P. C. S. is indebted to NRC (Canada) for support.

On the Formation of the Solar System

THE object of this article is to point out the significance of some properties of Jupiter (the most massive planet in the solar system) for the problem of the origin of the solar system. The mass of Jupiter is 0.001 solar masses, and its orbital eccentricity is 0.05. The following discussion shows that these properties of Jupiter are primaeval, and that they have not been affected by the evolution of the solar system.

I shall start by considering what would happen to the planetary system if the mass of Jupiter and/or the eccentricity of its orbit around the Sun increased Shelus and I[1] and Shelus (unpublished) have already tried to answer this in a study of the elliptical restricted problem of three bodies. Periodic orbits for a body of infinitesimal mass in the presence of two massive objects, moving around each other in eccentric orbits, were computed. The mass ratios for the two primaries used in this study were 1,000, 100, 10, 5, and 1. The periodic orbits were tested for stability under the framework of a linear stability analysis. From these computations, it is clear that increasing the mass of Jupiter and/or increasing its orbital eccentricity makes the orbits of the "small" planets, such as the Earth, unstable. A small planet, when put in one of the unstable orbits, will tend to collide with one of the primaries, or it will be thrown out of the system. Some stable periodic orbits exist, but they are located either very close to one of the two primaries or very far away from both of them.

If Jupiter had originally possessed 40 or 50 times its present mass, it would have made the planetary system unstable over a period much shorter than 4.5×10^9 yr. The planetary system would also have become unstable if Jupiter's orbital eccentricity were as small as 0.5. It should be mentioned that the increase of the eccentricity tends to destroy the stability of the orbits of the small planets more effectively than does the increase of the mass of Jupiter. Thus the fact that the planetary system has survived for a period of 4.5×10^9 yr leads us to the conclusion that the above mentioned properties of the most massive planet (Jupiter) are original properties of the system. If they are original, then any satisfactory theory of the formation of the solar system must take them into account.

The above discussion is obviously relevant to the problem of the existence of other planetary systems in the Galaxy. It is clear that double stars, which normally have mass ratios in the range 1 to 10 and eccentricities as high as 0.9, cannot possess planetary systems such as our own. Further, double stars, such as Lalande 21185, in which one of the components is a low mass "dark" star, may not possess planetary systems similar to our own, for their mass ratios are in the range 10 to 50, and the eccentricities in the range 0.3 to 0.9. The number of multiple stars in the Galaxy is very high, and at least 60% of all stars in the solar neighbourhood are found in double systems[2]. As the formation of double stars seems to be favoured, the occurrence of planetary systems cannot be a universal phenomenon. We may conclude that the total number of planetary systems in the Galaxy is probably much smaller than that estimated by some workers[3].

I thank Professor H. Bondi and Dr P. Shelus for discussions.

Dust transported in the North-east and South-east Trade Winds in the Atlantic Ocean

THE dust in the atmosphere over the oceans can yield an insight into the processes of deep-sea sedimentation and into certain aspects of oceanic pollution[1-4]. The importance of wind transport for the introduction of land-derived material to the oceans varies from one area to another, and the highest reported content of dust is found in the north-east trade wind system over the North Atlantic Ocean[5], but there seem to be no data on the dust loadings in the south-east trades of the Atlantic. To establish the concentrations and kind of dust in this important wind system, collections were made during July and August 1970 in both the SE and NE trades of the Atlantic Ocean between about 16° S and 23° N.

The dusts were collected on nylon meshes, and the volume of wind passing through the meshes was calculated using a calibrated anemometer. Two meshes, each 1 m^2, were exposed for each collection and the weights of dust collected were corrected for the collection efficiency of the meshes, which was assumed to be 50% (ref. 1). Samples with a prefix SH were collected in the SE trades off the coast of St Helena from a small fishing boat; those with a prefix GH were collected on the RMMV Good Hope Castle. The ship's track, collection areas and dust loadings are shown in Fig. 1, and collection details are given in Table 1.

Dusts collected in the SE trades between about 16° S and the equator have an average concentration of 0.55 $\mu g\ m^{-3}$ of air, and are predominantly brown or grey in colour. With the exception of dust GH3, which contained some shipboard contaminants, the dust loadings are quite similar and have only a relatively small range of concentration (0.33–0.70 $\mu g\ m^{-3}$ of air). Sample GH4 was collected in variable winds of the intertropical convergence zone, and has a similar dust loading to the SE trades. This sample, however, has a distinct red–brown colour, suggesting an origin for much of the dust in the deserts of West Africa. There was a dramatic change in dust loadings when the ship entered the NE trades; the red–brown dusts have an average concentration of 24.5 $\mu g\ m^{-3}$ of air.

Table 2 Particle Size Analyses of the Dusts*

Sample	<2 μm	2 to 4 μm	4 to 8 μm	8 to 16 μm	16 to 32 μm	>32 μm
Average of Dusts SH1 to SH5	74	14	9.0	2.0	1.0	Trace

GH6	84	6.8	4.8	2.6	1.2	0.6
M1†	79	13.5	6.5	1.0	Trace	Trace

* Particle size determinations were made by a microscopic counting technique, and the results are given as the percentage number of particles in each size class. The analyst was L. R. Johnson.

† M1 dust collected off West African coast between 17° 39′ N, 16° 36′ W and 18° 55′ N, 17° 22′ W—see ref. 5 for collection details. The particle size analysis given in ref. 5 was on a weight percentage basis and differs from that given here which is based on percentage number of particles.

The particle size analyses of the dusts are given in Table 2. Dusts collected to the south of St Helena have only a trace amount of material in the size class >32 μm. By contrast, dusts GH1, GH2 and GH3 contain more material both in the >32 μm and the 8 to 16 μm size range; this is probably the

Table 1 Dust Collection Details

Sample	Location*	Wind system	Colour of dust	Dust loading ($\mu g\ m^{-3}$ of air)	Remarks
SH1	Off the coast of St Helena Island, position 15° 54′ S to 16° 01′ S and 05° 37′ W to 05° 46′ W	SE trades	Light brown	0.78	Winds SE to SSE
SH2		SE trades	Brown–grey	0.33	
SH3		SE trades	Brown–grey	0.51	
SH4		SE trades	Light brown	0.54	
SH5		SE trades	Brown	0.37	
GH1	13° 19′ S, 08° 41′ W 08° 16′ S, 14° 36′ W	SE trades	Light grey	0.44	Wind SE
GH2	08° 16′ S, 14° 36′ W 06° 08′ S, 14° 42′ W	SE trades	Grey	0.51	Wind SE. Some contamination from ship smoke; dust loadings therefore represent upper limits.
GH3	06° 08′ S, 14° 42′ W 00° 00′ S, 16° 00′ W	SE trades	Grey–black	0.93	
GH4	00° 00′ S, 16° 00′ W 12° 27′ N, 17° 28′ W	Doldrums	Red–brown	0.51	Winds variable
GH5	12° 27′ N, 17° 28′ W 20° 20′ N, 17° 43′ W	NE trades	Red–brown	23	Winds NNE
GH6	20° 20′ N, 17° 43′ W 23° 09′ N, 17° 05′ W	NE trades	Red–brown	26	Winds NNE

* For samples GH1 to GH6 the location given is the ship's position at the start and finish of each collection.

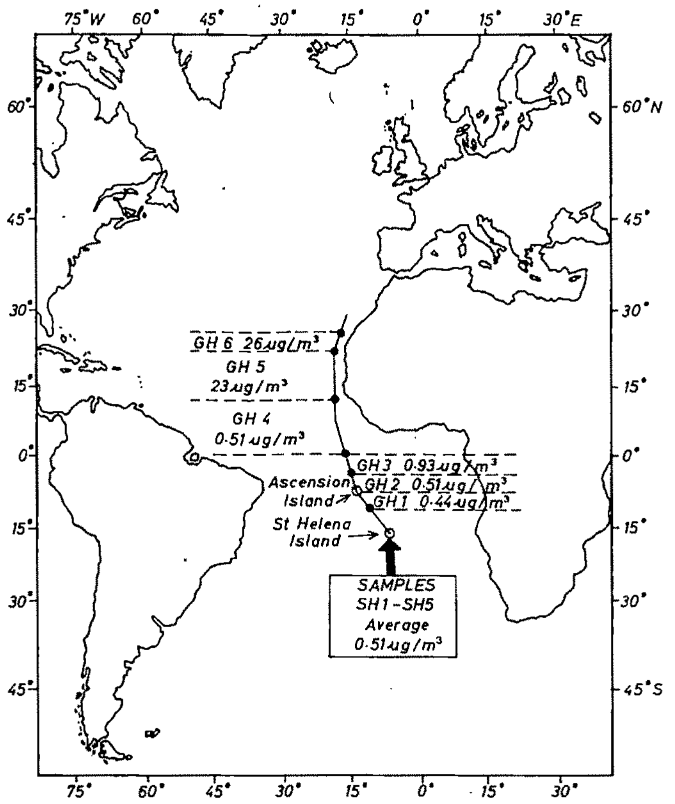

Fig. 1 Collections of atmospheric dusts in the south-east and north-east trade winds. The solid line indicates the partial track of the RMMV Good Hope Castle. The sample reference numbers are given together with the atmospheric dust loadings (calculated assuming a 50% mass collection efficiency).

result of an injection of material into the local atmosphere from the islands of St Helena and Ascension. Dusts GH5 and GH6 have a particle size distribution very similar to that of other dusts collected in the same area (Table 2). Sample GH4 has a larger proportion of small sized particles than either GH5 or GH6. The colour and mineralogy of GH4 indicate that a large proportion of the dust has the same origin as GH5 and GH6, that is, West African deserts, but it will have lost some larger sized material because it has been transported for a greater distance.

The mineralogy of some of the dusts is given in Table 3. The mineralogy of aeolian dusts has been widely reported in the literature[1,2,3,5] and only those features which highlight the differences between dusts of the NE and SE trades will be mentioned here. (1) It has been suggested[1] that dolomite probably from the Sahara Desert region characterizes NE trade wind dusts. Our data further indicate the usefulness of this mineral as an indicator of a Sahara Desert origin as it was not identified in any of the dusts from the SE trades; (2) the principal difference in the <2 µm clay mineralogies of the NE and SE trade wind dusts is that montmorillonite is far less abundant in the last of these. In South Atlantic deep-sea sediments montmorillonite has its highest concentration in mid-ocean areas where it constitutes between 30% and 50% of the total <2 µm clay minerals[7]. This has been interpreted in terms of either an aeolian input of montmorillonite or the *in situ* formation of this mineral from volcanic material of the Mid-Atlantic Ridge[7,8]. Our results indicate a relatively low montmorillonite content for South Atlantic dusts and support the hypotheses of the *in situ* formation of this mineral from local volcanic debris.

Our data and those given in the literature allow a tentative comparison between the dust-carrying capacities of the NE and SE trades of the Atlantic Ocean. The NE trades have a large reservoir of loose surface deposits in the desert areas of West and North Africa. Such an origin is reflected in the reddish colour usually shown by these NE trade dusts. Both the Kalahari (an inland desert) and the Namib (a coastal desert), both in southern Africa, could act as a source of dust for the SE trade winds. It has been shown[1,9] that dust originating in the Sahara Desert can be transported in relatively large quantities about 6,000 km westwards across the Atlantic. For example, dust-loadings at Bermuda in summer averaged about 6 µg m^{-3} of air. The influence which the Sahara reservoir exerts on the dust loadings of the NE trades is apparently much greater than the combined effects of the Kalahari and Namib deserts on the SE trades. In the atmosphere off St Helena, which lies about 2,500 km from the coast of South West Africa, the average dust loading is approximately 0.51 µg m^{-3} of air. This dust loading was obtained from collections made in the southern hemisphere winter; dust loadings will vary considerably from day to day and season to season depending on local meteorological conditions. From the haze-frequency distribution maps given by MacDonald[10] it can, however, be seen that the 5% isopath extends further from the coast of Africa in the southern hemisphere winter than it does in summer, that is, the winter dust loadings which we have obtained are likely to be an average upper limit for the yearly South Atlantic dust concentrations in this area.

To assess fully the effect of the Kalahari and Namib deserts on dust loadings of the SE trades, collections must be made southwards of St Helena towards the Namib coast of South

West Africa. Our data does indicate, however, that in mid-ocean areas the deposition of eolian material from the SE trades probably has a much smaller effect on deep-sea sedimentation in the South Atlantic than it does from the NE trades of the North Atlantic.

We thank HE the Governor of St Helena for permission to use the island as a sampling base, Mr A. W. Mawson and Mr A. Thornton for assistance, the directors of the Union Castle Line for permission to collect dust samples on board their ships, and the master, officers and crew of the RMMV Good Hope Castle for making collections and the Royal Society and the Air Pollution Control Office, US Environmental Protection Agency for financial support.

Recognition of Upper Miocene Neogene Zone 18, Experimental Mohole, Guadalupe Site

CORRELATIONS of marine strata using the convenient numerical zones of the Neogene[1,2], based on planktonic foraminiferans, represent an important advance in refining and developing greater precision in biostratigraphic correlations. This zonation is most effective in tropical and subtropical regions where the nominate planktonic taxa are best developed; progressive difficulty is encountered in applying it away from equatorial areas as these taxa disappear and are replaced by temperate and then by cold-water populations in polar areas. The experimental Mohole (Fig. 1), drilled near Guadalupe Island off Baja California, is significant as far as tropical-temperature planktonic foraminiferal populations are concerned because it is located in a subtropical area in which there is a commingling of tropical and temperate planktonic species[3].

Although studies have already been made of the experimental Mohole foraminiferans[3–5], the section was reanalysed in terms of Neogene Planktonic Zones (Fig. 2). The uppermost Miocene zone, Neogene Zone 18, is of special importance for three chief reasons which are relevant to the geologic history of the eastern Pacific. First, it is the uppermost zone of the Miocene and it is now possible to correlate Neogene Zone 18 of the standard numerical system for the tropics with the experimental Mohole section and in turn with the uppermost Miocene of California—the uppermost Mohnian and Delmontian Stages—using concurrent ranges of the tropical species *Globorotalia tumida plesiotumida* Banner and Blow (Fig. 3) and its descendant *Globorotalia tumida tumida* (Brady)[6]. Neogene Zone 18 can also be defined in the uppermost Messinian, the type upper Miocene of Italy[7,8]; this is a critical aspect for interregional correlations. Second, Neogene Zone 18 has been correlated with the upper Gilbert and lower Gauss Magnetic Epochs[9], the upper boundary being approximately at 3 m.y. or perhaps slightly more. This is in agreement with the 4.3 m.y. dating[10] for the Delmontian of the Mohole (Fig. 2). Third, the opening of the Gulf of California about 4 m.y. ago[11] allowed late Miocene–early Pliocene planktonic biofacies to enter the Gulf and to penetrate to the head of the Gulf before the end of the Miocene; the development of the northern Gulf before the opening at the mouth, as suggested by Larson and others[11], is not required.

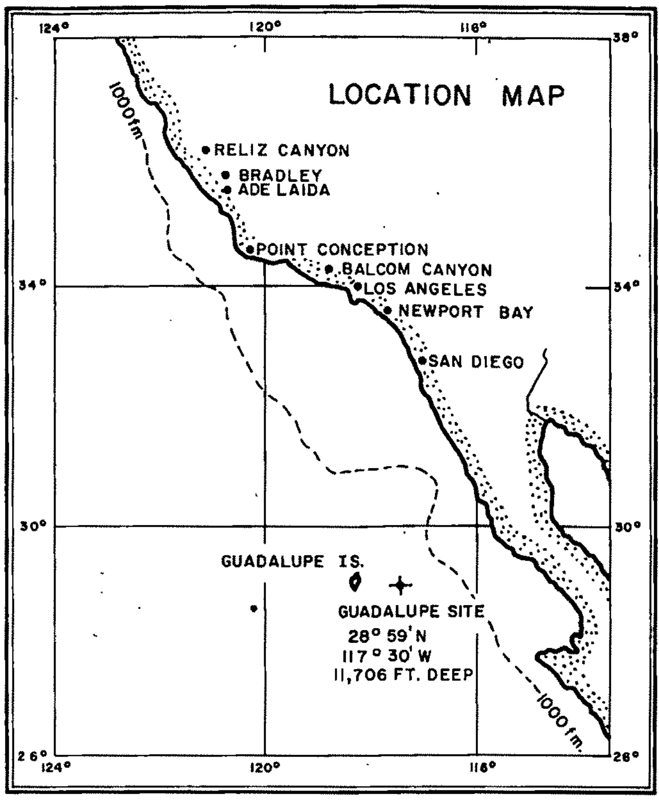

Fig. 1 Location of the experimental Mohole (Guadalupe site).

The marine deposition rates of many land-based sections are related to the definition of the upper limit of Neogene Zone 18, uppermost Miocene, with respect to southern California geology. The Ventura Basin[12], for example, has between 5,000 and 6,000 m of Pliocene–Pleistocene strata and the Los Angeles Basin[13] has not more than 3,000 m of section in the Pliocene–Pleistocene. Correlation of Neogene Zone 18 with the uppermost Gilbert and lower Gauss Magnetic Epochs suggests that there is a deposition rate of between 1,000 and 2,000 m per million years[14]. These basins, which are actively subsiding and have nearby sediment sources, exhibit rates from two to more than four times greater than those suggested for the Plio–Pleistocene of New Zealand[15]. They are compatible with rates indicated for the modern Santa Barbara Basin[16] and are many times greater than those computed for the Miocene of California.

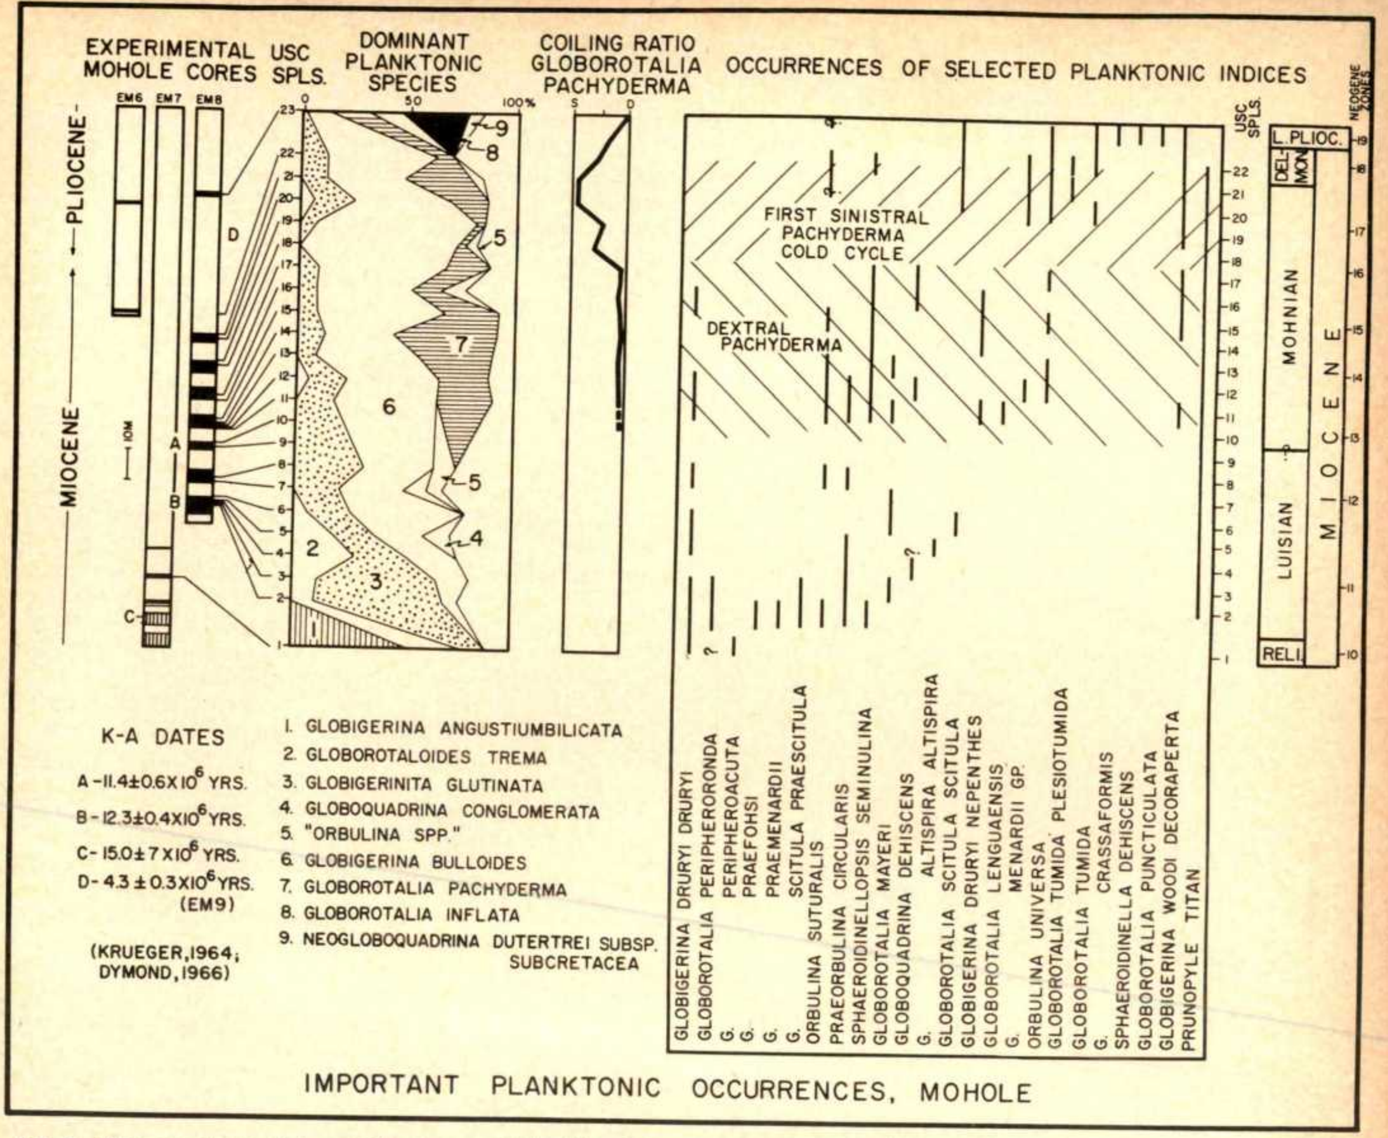

Fig. 2 Neogene planktonic foraminiferal zones (right side of figure) with important planktonic indices of the experimental Mohole showing coiling ratios of *Globorotalia* (*Turborotalia*) *pachyderma* (S, sinistral coiling; D, dextral coiling), the frequency distribution of common and abundant species, and the relative rare species as a bar graph. All are planktonic foraminiferans except *Prunopyle titan*, which is a radiolarian. K–A dates A, B, and D are those of Dymond[10] and C is from Kreuger[17]. This figure is from Bandy[8] as restudied and modified from that of Bandy and Ingle[3]. As noted in more complete analyses[8], Neogene Zone 13 marks the development of *G.* (*T.*) *pachyderma* just above the *Discoaster kugleri* zone; Neogene Zone 14 is defined by the concurrence of *Globorotalis* (*T.*) *mayeri* and *Globigerina druryi nepenthes*; Neogene Zone 17 is the level of maximum cooling, indicated by the dominance of sinistral populations of *G.* (*T.*) *pachyderma;* and Neogene Zone 18 is defined by the concurrence of *G. tumida tumida* and *G. tumida plesiotumida*.

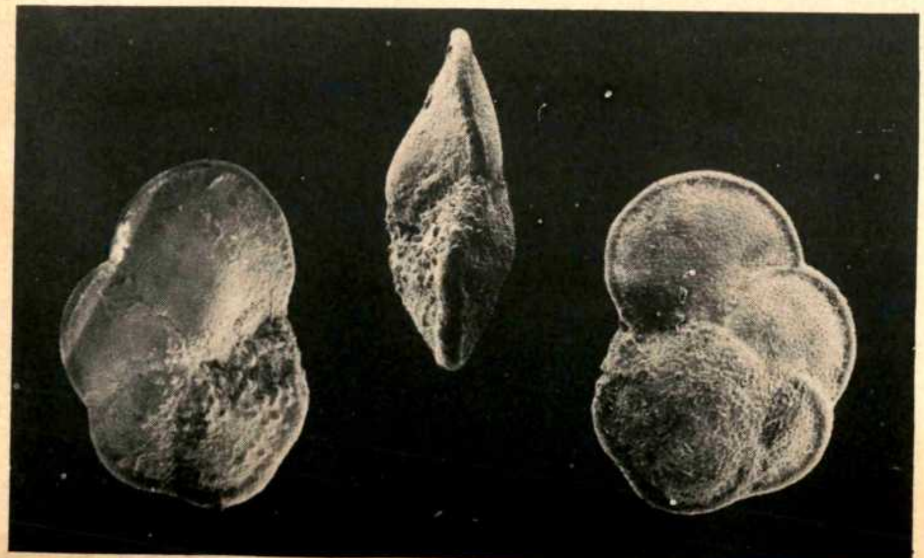

Fig. 3 *Globorotalia tumida* (Brady) subspecies *plesiotumida* Banner and Blow from USC sample 21, experimental Mohole section, Guadalupe site (Fig. 2). Specimen has a maximum diameter of 0.43 mm.

I thank Fritz Theyer for assistance in making the SEM photographs of *Globorotalia tumida plesiotumida* and the US National Science Foundation for financial support.

BIOLOGICAL SCIENCES

Allosteric Preconditioning: Role of Allosteric Ligands in Promoting the Maturation of Enzymes

THE tertiary structure of an isolated polypeptide chain may differ from its most stable conformation as a component of an oligomer. The assembly of free subunits into an oligomeric structure may therefore involve a relatively unstable oligomeric intermediate state in which the conformation of the subunits corresponds to that of the free polypeptide chains. Such a metastable intermediate state may be separated from the stable oligomer by a substantial energy barrier, and the marked temperature dependence of subunit association reactions has indeed been attributed to the existence of a "conformational transition state"[1].

We wish to focus attention on the surmounting of this energy barrier, that is, the transformation of an immature precursor of the enzyme, devoid of activity, into a form capable of catalysis (in the case of apoenzymes, a form capable of combining with the prosthetic group to yield an active enzyme). This process, which can be termed preconditioning, often seems to be affected by the ligands that also regulate the activity of the mature enzyme. We believe that this process, allosteric preconditioning, represents another general mode of regulation by allosteric ligands. Five specific examples reveal fundamental differences between the manner in which allosteric ligands affect preconditioning and the way in which they modulate the activity of the mature enzyme.

(1) Threonine deaminase, the biosynthetic enzyme from *Salmonella typhimurium*, can be reconstituted from the apoenzyme and pyridoxal phosphate. The resulting holoenzyme is, however, inactive until subjected to a maturation process. The rate of this process, especially at *p*H 7.5 and above, is greatly enhanced by valine or isoleucine, which are positive and negative effectors, respectively, of the active enzyme. On the other hand, the simultaneous presence of both effectors blocks the maturation process[2,3].

(2) Muscle phosphofructokinase can be inactivated by various means, including mild acidification and prolonged storage (refs. 4–6, and manuscript in preparation). The basis for the inactivation by mild acid is considered to be a dissociation into two subunits[4,6]. Activity is restored slowly at *p*H values above neutrality, but is markedly accelerated by certain ligands. ATP and ADP (which serve both as substrates and allosteric modifiers of this enzyme) are effective in the restoration of activity, but less so in the presence of Mg^{2+}. The positive effectors AMP and cyclic 3,5′-AMP also promote restoration. That it is the inhibitory site for ATP and not the substrate site that is involved in the preconditioning process is suggested by the interference of Mg^{2+} and by the fact that ITP, which is an excellent substrate but a poor inhibitor of this enzyme[7], is much inferior to ATP in reactivating the enzyme (manuscript in preparation).

(3) The behaviour of glycogen synthetase can be modified by phosphorylation and dephosphorylation, but the enzyme is also susceptible to the kind of conditioning we are concerned with. Thus, it has been shown with the liver enzyme that there are two mechanisms for the conversion of the D-form (dependent on high concentrations of glucose-6-P) to the I-form (relatively independent of glucose-6-P). One mechanism, which has been termed "direct", presumably involves phosphatase action. The "indirect" conversion, which is relevant here, proceeds through an intermediate, inactive state (produced by incubation at moderate temperatures in the presence of EDTA at alkaline *p*H[8]). Maturation of this to a catalytically active enzyme resembling the I-form is rapidly promoted by Mg^{2+} and $SO_3^{=}$, and by the allosteric effector of this enzyme, glucose-6-P[8,9].

A similar situation is observed in the case of pyruvate kinase. The enzyme from adipose tissue, which is dependent on FDP, can be rendered independent of that modifier by preconditioning in the presence of FDP. Interestingly, ATP, an inhibitor of the enzyme, interferes with the FDP-mediated preconditioning[10].

(4) Pyruvate carboxylase seems to provide an example of the preconditioning of an apoenzyme. A specific synthetase catalyses the transfer of biotin to apo-pyruvate carboxylase isolated from *Bacillus stearothermophilus*. This reaction is strongly dependent on acetyl CoA, which is also a positive effector of the holoenzyme. On the other hand, L-aspartate antagonizes the effect of acetyl CoA both in the synthetase reaction and in the carboxylation *per se*[11,12].

(5) Tryptophan pyrrolase provides a classical example of substrate-mediated enzyme maturation[13]. The rate of production of active holoenzyme from apoenzyme is enhanced by tryptophan about ten-fold[14], but the concentration of tryptophan required for half-maximal rate of apoenzyme combination with haemin is considerably below the K_m for tryptophan of the holoenzyme; moreover, α-methyltryptophan, neither a substrate nor an inhibitor of the holoenzyme, can effectively promote maturation[14]. This suggests that preconditioning of tryptophan pyrrolase involves the binding of tryptophan to an "allosteric" site rather than to the active site of the enzyme.

These examples reveal an important general feature of allosteric preconditioning: although allosteric ligands may promote the process, it can also occur in their absence, albeit much more slowly. Moreover, the continued presence of the maturation-inducing ligands is not required for the maintenance of the mature state, that is, maturation is essentially irreversible and thus the mature state must represent the thermodynamically more stable form of the enzyme. Allosteric ligands must therefore promote preconditioning not by stabilizing the mature enzyme but by enhancing the rate of conversion of the immature to the mature state (Fig. 1). This role of allosteric ligands differs fundamentally from their role in allosteric activation or inhibition of enzyme activity, which

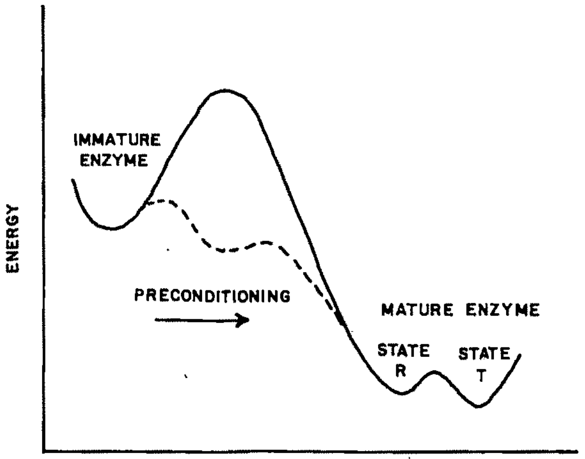

Fig. 1 Preconditioning of an enzyme in the absence (———) and in the presence (- - -) of a maturation-promoting ligand.

is mediated by the preferential stabilization of either an active or inactive form of the enzyme (that is, states R and T in Fig. 1)[1]. This difference is also illustrated by the fact that preconditioning, unlike allosteric inhibition or allosteric activation, can be promoted by either positive or negative effectors. Thus, either the positive effector valine or the negative effector isoleucine induces maturation of threonine deaminase, and phosphofructokinase is reactivated by adenine nucleotides including both positive and negative modifiers. Yet, in spite of the different mode of action of effectors in allosteric regulation of enzyme activity and in promoting enzyme maturation, it seems likely that in both processes the effectors bind to the same sterospecific site(s) on the enzyme. Direct evidence for this hypothesis must come from the study of the preconditioning of enzymes in which allosteric sites are altered by chemical modification or mutation. The observation that ATP promotes the conditioning of phosphofructokinase more effectively than ITP, which is in accord with the relative affinity of these nucleotides for the inhibitor site, supports such an idea.

Since allosteric preconditioning and allosteric regulation seem to involve the same site on the enzyme, it is important to distinguish allosteric preconditioning from the frequently observed stabilization of enzymes by allosteric ligands. The latter can be attributed to the fact that the catalytic centre of an enzyme may be more stable in one of the allosteric states of the enzyme (usually the inactive state), and thus any ligand that binds preferentially to this state will enhance the stability of the enzyme. The observation that either valine or isoleucine can promote the maturation of threonine deaminase, in spite of the fact that the positive effector valine (unlike isoleucine) reduces the stability of the enzyme[15], lends validity to this distinction.

If preconditioning or maturation were indeed obligatory in the biosynthesis of an active enzyme, as seems to be the case at least with threonine deaminase, pyruvate carboxylase and tryptophan pyrrolase, one might conclude that the primary function of allosteric sites is the binding of maturation-promoting ligands. Once such a site has evolved on a protein, the mature form of which could exist in several conformational states that differ in catalytic activity, it would be likely that the affinity of this site for its ligand would differ for each state, a situation that would subject the catalytic activity of the enzyme to regulation by the maturation ligand. In other words, allosteric regulation would be the frequent outcome of ligand-promoted preconditioning. Nevertheless, enzymes should exist where this evolution of preconditioning sites into regulatory sites has not yet occurred. Such an example may well be provided by liver tryptophan pyrrolase, where α-methyltryptophan promotes maturation by binding to a separate site but yet has no influence on the activity of the holoenzyme. On the other hand, in the enzyme from *Pseudomonas acidovorans*, the preconditioning site seems to have evolved into a regulatory site, for here α-methyltryptophan not only induces maturation but also acts as a positive allosteric effector of the holoenzyme[16].

The presence of maturation sites that have not yet evolved into regulatory sites may also account for occasionally observed enzyme-ligand interactions that are difficult to explain in physiological terms. For example, FDP specifically increases the thermolability of *Escherichia coli* β-galactosidase[17] but has no effect on the enzyme's activity. (Yet FDP is known to be an allosteric modifier of another catabolic enzyme in *E. coli*—glycerokinase[18].) Another effect which is difficult to rationalize physiologically is that of nonpolar L-amino-acids on aspartokinase. In *B. polymyxa*, nonpolar L-amino-acids act as weak activators[19], in *E. coli* as weak inhibitors[20], and in *B. subtilis* some nonpolar amino-acids activate while others inhibit aspartokinase (manuscript in preparation). These ligands may play a role in enzyme maturation rather than in the regulation of activity, and it should be of interest to determine whether the reconstitution of the enzymes from their polypeptide chains is not enhanced by these specific agents.

Interaction of enzymes with allosteric ligands is not the only way to effect preconditioning. As mentioned, variation of *p*H or the presence of various ions can also accelerate enzyme maturation, and substrates or coenzymes can also promote this process, as observed with several dehydrogenases[21–23]. We have focused our discussion on the role of allosteric effectors because the cited examples encourage the hypothesis that the preconditioning process may often be the antecedent of allosteric regulation. Moreover, the concepts proposed would provide a unified view of preconditioning phenomena and stimulate the search for such a process among allosteric enzymes and especially among those proteins which exhibit hitherto unexplained interactions with specific small molecules.

Chromosomal Localization of the Heterochromatic Region 16qh(.76) linked to α-Haptoglobin in Man

THE structural gene locus for the alpha chain of haptoglobin (α-Hp) in man seems[1] to be on the long arm (q) of chromosome 16 linked[2] to a fragile heterochromatically staining region (h). We here report measurements localizing this region, which we designate 16qh(.76).

16qh(.76) was found to be segregating in a large family[2]. From thirty-one of the family members heterozygous for 16qh, 1,709 lymphocyte metaphases were analysed microscopically and 801 metaphases photographed. Both chromosomes No. 16 were relatively straight and free of overlap by other chromosomes in 193 metaphases. Eighty of these metaphases showed 16qh clearly and were therefore selected for measurement.

Using photographic prints with a final enlargement of ×3,840, we measured the No. 16 chromosomes with a specially designed, manually operated wheel on which a millimetre scale was directly engraved (unpublished results of H. W., W. J. K., and F. H.). Both chromatids were measured and the results averaged. We measured the length of the short arm (p) from each chromosome No. 16, q from the normal homologous 16 ($q^{\text{homol.}}$), and the euchromatic parts of q proximal ($q^{\text{prox.}}$) and distal ($q^{\text{dist.}}$) to 16qh.

We compared the length of $q^{\text{prox.}}$ to $q^{\text{homol.}}$ in each cell and found the mean length of $q^{\text{prox.}}$ to be 0.759 of $q^{\text{homol.}}$ (s.e. = 0.011). Thus, the fragile heterochromatic site is approximately 76% of the distance along the long arm of No. 16. Since other heterochromatic regions may be located on 16q, we have designated this site 16qh(.76).

Table 1 One Way Analysis of Variance of the Length of the Distal Segment of the 16qh Chromosome

Source of variation	Degrees of freedom	Sum of squares	Mean squares	F ratio
Between person	31.0	0.6631	0.0213	
Within person	48.0	0.7215	0.0150	
Total	79.0	1.3846		1.422

We then tested whether 16qh(.76) detectably affected the length of euchromatin on that chromosome, using a paired observation *t* test. The mean length of p from the involved No. 16 was not significantly different from the mean length of p from the homologue ($t = 1.68$, df = 79, $P > 0.05$). The sum of the means of $q^{\text{prox.}} + q^{\text{dist.}}$ was, however, 2.6% greater than the mean of q from the homologue ($t = 2.17$, df = 79, $0.05 > P > 0.02$).

Finally, we tested for heterogeneity between persons in the length of $16q^{\text{dist.}}$ and found none. The F ratio (between person/within person variance) was 1.42 (Table 1), which is not significant.

The foregoing cytological data should not be interpreted to mean that the structural gene for α-Hp is necessarily located 76% of the distance from centromere. α-Hp could be cytologically at some distance from h(.76) but seem to be closely linked, if the heterochromatic region tended locally to suppress crossing-over. The data also cannot reveal if α-Hp is between the centromere and 16qh(.76) or distal to 16qh(.76).

Concurrent segregation analysis of chromosome markers (for example, 16qh(.76)) and gene markers (for example, α-Hp) permits the testing of map assignments deduced from studies with chromosome rearrangements[1] and the localization of specific genes to specific chromosome regions, as in the present study. The efficiency of chromosome marker work will predictably increase as chromosome variants are recognized more frequently. In this family we have recently observed the segregation of three other potentially useful variants (3 inv, 17qh and Ginv), as will be reported in more detail.

Interpretation of Linkage in Somatic Cell Hybrids

Kao and Puck[1] have measured the linkage between human genes by studying their association in cell hybrids with Chinese hamster cells which carried mutations homologous to the human genes. Such studies are made possible by the extensive loss of human chromosomes from such hybrids. If, however, one of the human genes is retained owing to the operation of specific selection, the presence or absence of an unselected gene gives a measure of linkage between them.

In one hybrid studied by Kao and Puck the human genes were inositol independence (*inos*$^+$) and proline independence (*pro*$^+$). Among forty-two clones selected for *inos*$^+$, only seven (one sixth) were also *pro*$^+$. In another hybrid the human genes were glycine independence (*gly*$^+$) and *pro*$^+$. Among fifteen clones selected for *gly*$^+$ only five (one third) were also *pro*$^+$. Both these experiments were interpreted as evidence of non-linkage between the pair of marker genes. I submit that such associations, though well below the 50% expected between unlinked genes in sexual hybrids, are nevertheless greater than would be expected from random association of the marked chromosomes in cell hybrids. The first problem is to determine what would be the extent of random association between two unlinked genes (that is, genes on separate chromosomes). This would depend on the number of human chromosomes still retained in the hybrid. In the first hybrid, because of the method of selection one chromosome must carry *inos*$^+$. If a second chromosome is present the probability that it will not carry *pro*$^+$ is 43/45. The chance that a third and fourth chromosome will also be free of *pro*$^+$ will be 42/44 and 41/43 respectively. In general terms, if a hybrid clone has *n* human chromosomes of which one carries *inos*$^+$, the chance of *pro*$^+$ being also present will be $1 - \dfrac{43!\,.\,.\,(45\text{-}n)}{45!\,.\,.\,(47\text{-}n)}$. When $n = 2$ the association of *inos*$^+$ and *pro*$^+$ will be 0.044 and increases approximately in proportion to $(n-1)$. The observed association of 0.167 would require an average of 5 human chromosomes in all clones. The association in the second hybrid of 0.33 between *inos*$^+$ and *gly*$^+$ would require the presence of ten human chromosomes, but Kao and Puck show an idiogram with seventeen hamster chromosomes and two "human" chromosomes (judged to be 2 and 6 or X under the Denver classification) and state that other clones had "similar karyotypes", and that all stabilized clones had nineteen, or occasionally twenty, chromosomes. The original Chinese hamster cell line had twenty chromosomes, so it seems that two human chromosomes have been substituted for three hamster ones. One is forced to conclude that the human chromosomes retained in the hybrids are much fewer than five, and the association found between the genes cannot be attributed to chance association of two chromosomes. Although there is only one kind of random association of chromosomes, there is a large number of non-random associations which might be considered. The simplest and most probable form of non-random selection arises from the fact that we are sampling from a diploid set with two representatives of each kind. It would seem likely that if a sample of chromosomes contains the haploid number (twenty-three) or less, it will not contain more than one of each homologue. This would produce only a slight modification of the fully random formula given above. The association of two markers among n chromosomes would become $1-\frac{21!\ldots(23\text{-}n)}{22!\ldots(24\text{-}n)}$. For an association of 0.167, n is still 5, and for an association of 0.33 it is 9. Such non-randomness is not, therefore, capable of explaining the associations found.

Another kind of non-randomness would arise if, though the chromosomes were lost at random, certain combinations were more viable than others. In cases where one chromosome was selected, the probability of any particular second chromosome being present would vary from more than random (0.044) to less than random according to the viability of the combinations. In the hybrids considered here, the *pro*$^+$ chromosome would seem to have a greater than random chance (four-fold and eight-fold respectively) of being included with the selected chromosomes *inos*$^+$ and *gly*$^+$.

Another non-random model assumes that human chromosomes are of two kinds, compatible and incompatible with the Chinese hamster genome. The hybrid karyotype suggests that compatible human chromosomes might be those which can be substituted for hamster chromosomes. If all the compatible chromosomes had equal chances of inclusion in the hybrids and their number was x, the chromosomes carrying *inos*$^+$, *pro*$^+$ and *gly*$^+$ must be among that number. The chance of any one compatible chromosome carrying *pro*$^+$ will therefore be $2/x$. The first chromosome has been determined by the method of selection. The chance that the second one will carry *pro*$^+$ will be $2/(x-2)$. The data give us two estimates of x: 14 when *inos*$^+$ is selected and 8 when *gly*$^+$ is selected, with a best estimate of 11. In other words, out of forty-six human chromosomes only eleven are compatible with the Chinese hamster genome. The concept of incompatible human chromosomes opens up further possibilities. If the gene being selected for in the hybrid were on an incompatible chromosome, it could be retained, but only by a structural change; by being translocated onto a host chromosome, onto a compatible chromosome of the other parent, or by deletion of the "incompatible segment". It would then become very difficult to identify the chromosome carrying the human gene and even more difficult to identify the chromosome from which it was derived. Pursuing the model further, the association found between genes could be due to their presence on the same human chromosome, the degree of association being determined by the classical map distance between them; that is, by the chance that the break which enables the selected gene to be retained in the hybrid will also include the associated gene.

The karyotype presented as typical by Kao and Puck was interpreted by them as having three hamster telocentrics replaced by two human metacentrics. Another possibility is that the two new chromosomes represent rearrangements between three hamster telocentrics and one arm of a human chromosome. Such spontaneous rearrangement may seem an unlikely explanation but many spontaneous rearrangements accompanied the origin of the permanent Chinese hamster cell line, eight out of twenty chromosomes of which do not resemble any chromosomes in the primary explant. Moreover, the extreme selection pressure operating in favour of human wild type genes would fix any rare events which increased their chance of survival. This is the probable explanation of the high degree of dissociation in man–mouse hybrids between two human genes known to be sex-linked (HGPRT and G6PD) when only one of them is subject to positive selection[2]. If the association of *pro*$^+$ with *inos*$^+$ and with *gly*$^+$ is due to location on the same human chromosome, the strength of the association indicates the map distances and the gene order, which would be *pro gly inos* or *gly pro* . . *inos* (*inos* being twice as far as *gly* from *pro*).

This model fits evidence from an entirely different source. It has been argued[3] that the isolation of recessive mutants in Chinese hamster near-diploid cell lines is due to the existence of chromosome segments in the monosomic condition, so that there are no dominant wild type alleles to mask the mutations. Such mutations would be confined to few segments or even to a single chromosome segment. The location of the mutant genes *pro*$^-$ *inos*$^-$ and *gly*$^-$ on one segment of hamster chromosome would then be paralleled by the location of the genes *pro*$^+$ *inos*$^+$ and *gly*$^+$ on one segment of human chromosome.

To conclude, the association found by Kao and Puck between *inos*$^+$ and *pro*$^+$ and between *gly*$^+$ and *pro*$^+$ in Chinese hamster/human hybrids is greater than would be expected from the random association of two chromosomes. Three possible causes of such an association of the human genes have been considered.

If the associated pairs of genes are on different human chromosomes, these chromosomes must be associated, (*a*) because of some genetic interdependence, such that the presence of one increases the probability that the other will also be present; (*b*) because of some specific compatibility that both share with the hamster genome (for example, ability to substitute for hamster chromosomes); (*c*) both genes may be located on the same human chromosome, but this chromosome has a high incidence of rearrangement in hybrids. Theoretically, these explanations seem to be equally valid. They require to be tested by further genetic studies in cell hybrids combined with intensive karyotyping.

Activation of a Central Noradrenergic Projection to Cerebellum

RECENT histochemical studies have demonstrated abundant nerve fibres containing noradrenaline in rat cerebellar cortex[1,2] terminating predominantly on Purkinje cells[2]. An inhibitory function for these fibres is suggested by the uniform inhibition of the spontaneous discharge[3] and hyperpolarization of Purkinje cells (P cells) produced by microelectrophoretic application of noradrenaline (NA)[4]. Furthermore, the firing rate of Purkinje cells is generally increased after destruction by 6-hydroxydopamine of fibres containing NA[5]. Further characterization of the natural endogenous transmitter and its effect on P cells requires experimental activation of the proposed adrenergic pathway, and identification of the origin of the NA projection to the cerebellum thus assumes critical importance. It has been suggested that the nerves containing catecholamine in rat cerebellar cortex arise largely from discrete bilateral nuclei of fluorescent cells in the dorsal medullary brain stem (the locus coeruleus, LC)[6,7]. We have reported that electrical stimulation in the area of the LC inhibits P cells[8]. We now report that this inhibitory response is evoked selectively from the NA-containing cells of the LC, that the inhibitory effects are widespread and that the response closely resembles the electrophysiological effects produced by exogenous NA.

Male albino rats (130–230 g) were anaesthetized with halothane. The cerebellar vermis and one hemisphere were exposed[3]. A fine (0.4 mm) concentric bipolar stimulating electrode was inserted through the hemisphere at an angle of 29° from the vertical into cerebellar and brain stem loci after empirical stereotaxic localization of the LC. The location of the electrode was verified histologically after each experiment. Purkinje cells, identified by their characteristic climbing fibre bursts[9], were recorded in the cerebellar vermis with extracellular micropipettes (2 M NaCl, 1–8 MΩ) or intracellular micropipettes (3 M KCl, 10–40 MΩ). Responses to brain stimulation (0.1 ms pulse duration) were recorded on magnetic tape. Mean firing rate (spikes s^{-1}) was displayed with a pen recorder[3]. Post-stimulus time histograms (PSTHs) were generated by a Digital PDP-12 computer. Mean arterial pressure was monitored during LC stimulation and showed no change.

Purkinje cells, but not cortical interneurones, showed a remarkably uniform inhibitory response to stimulation of LC with trains of pulses: ninety-four of 102 cells (twenty animals) recorded extracellularly displayed depression of spontaneous discharge rate (Fig. 1*A*, *B*). This summated response was greatest at relatively low stimulus frequencies (3–50 s^{-1}) and was markedly diminished at faster rates. Complete cessation of discharge outlasting the stimulation period by 4–65 s (mean, 21 s) could be obtained with 20–100 pulses at 10 s^{-1}. At this frequency, threshold currents ranged from 0.03 to 1.2 mA (mean, 0.35 mA).

Although the response to a single LC stimulus often escaped detection on direct visual inspection, construction of PSTHs reproducibly revealed reduced probability of spike discharge over prolonged intervals of 60 to 470 ms (mean, 293 ms) with long latent periods of 50–290 ms (mean, 148 ms). During these late inhibitions, cell discharge was often only incompletely suppressed; however, a single short burst of two to five pulses at high frequencies (20–75 s^{-1}) usually resulted in a complete pause in firing (Fig. 1*C*).

Stimulation of LC often produced short term (5–10 ms) activations of P cells (preceding the late inhibitory period), consisting either of single spikes, climbing fibre bursts, or, more frequently, simple or complex field potentials without obvious spikes. These rapid responses had latent periods ranging from 1.5–11 ms, and were often immediately followed by short inhibitory periods of 10–60 ms (mean, 18 ms). These early events may result from current spread to other brain stem areas (for example, brachium conjunctivum), because (i) many P cells exhibiting late inhibition showed no such responses, and (ii) dissociation between the long inhibitory responses and the activations and/or fields could often be produced by fine adjustment of the stimulating current or by specific drug administration (B. J. H., G. R. S., F. E. B., and A. P. O., in preparation). However, a direct connexion (via collaterals, for example) from LC to some cells of origin of mossy or climbing fibres cannot be ruled out at present.

Intracellular recording of some P cells during stimulation of LC with single shocks revealed late hyperpolarizations (not directly related to climbing fibre responses) which were usually weak or nearly lost in baseline noise (Fig. 2*A*, broad arrow). Signal averaging techniques better delineate these small late hyperpolarizing responses (0.5–2 mV), which are comparable in latency and duration to the late prolonged periods of suppression seen in post-stimulus histograms (Fig. 1*C*).

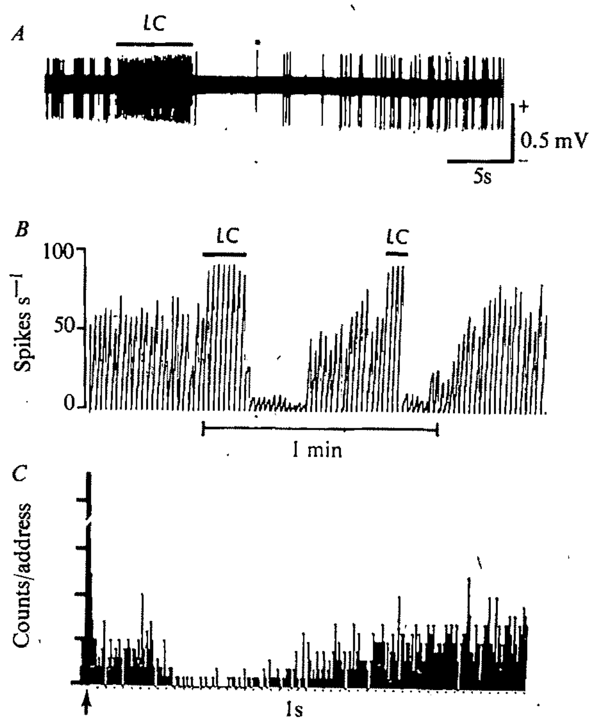

Fig. 1 Extracellular responses of P cells to stimulation of locus coeruleus (LC). *A*, Oscillograph record of action potentials; response to fifty-seven shocks (0.25 mA) delivered to LC at 10 s^{-1} (solid bar above action potentials). A climbing fibre response to a single LC test stimulus is indicated by the dot above the record. *B*, Polygraph record showing integrated discharge frequency of another Purkinje cell. Firing rate drops to zero with multiple shocks (100 and 50 pulses, respectively; 10 s^{-1}; 0.32 mA) to LC (solid bars above record). Apparent excitation seen during stimulation results from addition of the multiphasic stimulus artefact. *C*, Post-stimulus time histogram of the response of another P cell to single short bursts of shocks (0.28 mA, 3 pulses at 75 s^{-1}) delivered to the LC every 2.1 s (sixty-four sweeps). Arrow shows stimulus artefacts. Each marker on ordinate = 5 counts/address. Address or bin size = 4 ms.

With trains of pulses, large hyperpolarizations extending well beyond the stimulation period and averaging 14 mV (range, 2–39 mV) were recorded (Fig. 2*B*). An index of membrane resistance was obtained by measuring the size of climbing fibre spikes (see refs. 4 and 10)—or in obviously injured cells excitatory postsynaptic potentials (EPSPs), and by measuring the potential deflexions produced by hyperpolarizing currents (0.5–1 nA, 40 ms duration) passed through the recording micropipette in conjunction with a Wheatstone bridge circuit[11]. In all cases, input resistance, as measured by these two parameters, either increased (ten cells) or did not change (two cells; Fig. 2*B*) during the LC evoked hyperpolarizations. Hence, this hyperpolarization does not seem to result from activation of a conventional inhibitory pathway (for example, parallel fibre activation of basket cells), for a decrease in resistance would then be expected[9]. In this respect, LC stimulation exactly mimics the action of exogenously applied NA and cyclic AMP, which also produce hyperpolarizations without a decrease in membrane resistance[4]. But other mechanisms such as presynaptic inhibition, or disfacilitation, although less likely to evoke such

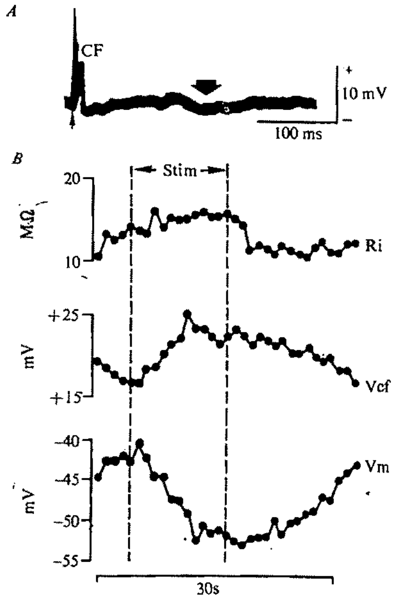

Fig. 2 Responses of P cells to stimulation of LC: intracellular recording. *A*, Oscillograph record of response to a single shock (small arrow; 0.7 mA). This supramaximal stimulus drives a climbing fibre evoked EPSP (CF) followed immediately by an early after hyperpolarization and finally a late, more prolonged hyperpolarization (broad arrow). *B*, Graph of intracellular response to stimulation of LC (Stim) with multiple shocks (0.45 mA, 120 pulses at 10^{-1}). Records were analysed at 1 s intervals by a PDP-12 computer, and the results for input resistance (Ri), size of climbing fibre responses (Vcf) and membrane potential (Vm) plotted against time. Although the input resistance did not change appreciably during this test, in the two other tests recorded in this cell, resistance increased by 164 and 295%.

large and widespread responses, might also produce the observed effects.

The anatomical discreteness of brain stem loci evoking this characteristic inhibitory response is underscored by the finding that the incidence of depression of P cell discharge falls abruptly when the stimulating electrode is placed slightly outside of LC (Table 1). In many cases, individual cells which responded when the electrode was in the LC failed to do so when the stimulation electrode was displaced from the LC by as little as 0.5 mm; recovery of response ensued with repositioning in the LC. Furthermore, when catecholamine-containing pathways were selectively and chronically destroyed by intracisternally-injected 6-hydroxydopamine[2,12], only five of sixty cells were inhibited (Table 1) when the LC was stimulated directly (seven animals) (B. J. H., G. R. S., F. E. B., and A. P. O., in preparation).

It might be argued that the late inhibitory responses to single shock stimulation of LC allow for conduction of impulses through many possible synapses, rather than the proposed monosynaptic noradrenergic pathway. A large portion of the long latent period, however, may be due to a long synaptic delay, such as those of 30–100 ms described for the slow inhibitory postsynaptic potentials (IPSPs) of sympathetic ganglia[13,14]. The slow IPSP, like the proposed LC-Purkinje cell inhibition, is conceived as an adrenergic response[15]. Moreover, the catecholamine-containing fibres to cerebellum are small C-fibres[2], which should conduct impulses very slowly. Conduction velocities for small peripheral C-fibres may range from 0.15 to 0.5 m s^{-1} (ref. 16). Finally, the neuroanatomical data suggest a direct LC projection to P cells[3,6–8].

Furthermore, the LC evoked inhibition of P cells shares many properties of peripheral autonomic systems, such as the relative efficacy of trains of pulses over single shocks[13–15,17], a diminished responsiveness at high stimulus frequencies[17], and hyperpolarizing responses without decrease in resistance[15].

In view of early reports[18] emphasizing the sparseness of catecholamine-containing fibres in the cerebellum, perhaps the most surprising finding of this study is that nearly all Purkinje cells recorded in the vermis exhibited the inhibitory response to LC stimulation. Almost all the cells in the LC of the rat contain noradrenaline[19] and noradrenaline always inhibits Purkinje cells when applied exogenously[3], so the proposed adrenergic projection from LC to cerebellar cortex may assume a greater functional significance than previously supposed. Pharmacological evidence supporting the noradrenergic nature of this projection will be reported separately.

We thank Drs R. Nicoll, S. Koslow, and A. Padjen for criticisms.

Regeneration of Porphyropsin *in vivo*

SCOTOPIC vision is mediated by the rod cells of the retina which contain a photosensitive pigment that (according to species) can be rhodopsin, porphyropsin, or a mixture of both. The pigment content may be diminished by exposure to light, but there is no permanent loss because the light-decomposed molecules are restored by regeneration. Although the time course and some details of the mechanism of rhodopsin regeneration *in vivo* are well known[1], we have little and contradictory information about the regeneration of porphyropsin. According to Kühne and Sewall[2] and Abelsdorff[3], the porphyropsin-like pigment in the retina of the living bream (*Abramis brama*)[4,5] is regenerated within 30–40 min. Garten[6], however, who worked with the same fish, found regeneration to be complete after not less than 4 h. I have found a similar figure for regeneration of porphyropsin in the retina of crucian carp (*Carassius carassius*).

Crucian carp were used because their porphyropsin is not paired with rhodopsin[7]. In each experiment, four or eight animals of equal size (12–13 cm long) were light-adapted for 1 h in a transparent plastic tank (20 × 20 × 30 cm) illuminated by five reflector flood-lamps (light output per lamp, 1,950 lumens, colour temperature about 2,730 K). This light bleached about 70% of the pigment. The temperature during light adaptation was 16–17° C and 15.0 ± 0.3° C during subsequent dark adaptation. The dark periods lasted from 30 min to 5 h. To estimate the full pigment content of the fish eyes, some animals were dark-adapted overnight. Several precautions were taken to prevent regeneration during dissection and washing. After the fishes had been killed, the eyes were removed as quickly as possible and put on a block of solid carbon dioxide—a procedure which took about 4 min for six eyes. Subsequently, the retinas were dissected out into a Petri dish filled with an ice-cold solution (*p*H 4.5) consisting of a 1 : 1 mixture of McIlvaine buffer (*p*H 4.6) and 0.2 M hydroxylamine solution. The same cooled solution (2° C) was used to wash the retinas and the receptors. The 0.1 M hydroxylamine buffer solution served also as the solvent for the digitonin that was used as an extractant in a concentration of 3%. It was shown in some preliminary experiments that the relatively high concentration of hydroxylamine had no influence on the yield of pigment, nor did it diminish the stability of the extracts. Double extractions were made in all experiments, the first extracts contributing some 75% and the second ones approximately 20% to the total pigment yield.

The unbleached extracts exhibit two well defined absorption peaks at about 520 nm and between 355 and 360 nm (Fig. 1). The former is the easily identifiable porphyropsin peak, the latter is presumably caused by 3-dehydroretinol, the all-*trans*-isomer of which has a λ_{max} of 350 nm. The second absorbance maximum shifts to shorter wavelengths when the extracts are prepared from retinas which have been left in darkness for comparatively short periods. In these conditions the ultraviolet peak was found near 352 or 353 nm and its height was somewhat greater. Although porphyropsin and presumably impurities contribute to the ultraviolet peak, its height may be taken as roughly proportional to the amount of 3-dehydroretinol present in the extracts (line *B* in Fig. 1). The absorbance change on bleaching at 520 nm (line *A* in Fig. 1), on the other hand, indicates the amount of porphyropsin present. The sum of *A* plus *B* was fairly constant in all the extracts (($A+B$) ± s.d. = 1.2015 ± 0.1964; N = 13) with the exception of those taken from fully light-adapted eyes. These were presumably contaminated with material extracted from the pigment epithelium, for it was difficult to obtain clean retinas in these experiments. The ratio of *A* to *B* increased with the duration of dark adaptation. A/B was as low as 0.05 in light-adapted retinas, it has the value 0.16 after 3 h of dark adaptation and approaches a figure of 0.30 in fully dark-adapted retinas (Fig. 1). If it is assumed that the material represented by the data was extracted chiefly from the receptors themselves, then the values for *A* and *B* permit the following conclusions to be made : (1) the retina of *Carassius carassius* stores some 3-dehydroretinol; (2) 3-dehydroretinal released from bleached porphyropsin and reduced to the alcohol is added to the store; (3) during regeneration, the prosthetic group is supplied by this same store because the ratio A/B increases by a factor of six or so while the sum $A+B$ remains constant.

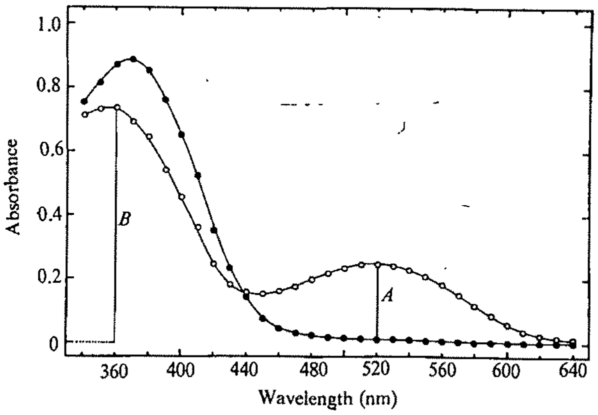

Fig. 1 Absorbance spectrum of a retinal extract from the dark-adapted crucian carp *Carassius carassius*. The data refer to a first extract from six retinas. The change from ○ (unbleached) to ● (bleached) is due to light exposure. The lengths of lines *A* and *B* are taken as respective measures of porphyropsin and 3-dehydroretinol.

Difference spectra derived from curves, like those in Fig. 1, peak at 522 nm (positive branch) and 385–388 nm (negative branch) indicating that dehydroretinal oxime is the principal product of bleaching (compare ref. 8).

The time course of regeneration is shown in Fig. 2. The points represent the amount of photosensitive material (λ_{max} = 520 nm) extracted from the retinas after various times in the dark. Although the data show appreciable scatter, the general trend is as follows: after a lag of approximately 1 h, regeneration begins slowly during the second hour. This is followed by 2 h of a fairly constant rate of increase of pigment until eventually regeneration approaches virtual completion during the fifth hour of darkness.

The mechanism that causes the long initial delay of regeneration is unknown. Regeneration of rhodopsin in the living frog is similarly delayed, but for not more than 15–20 min.

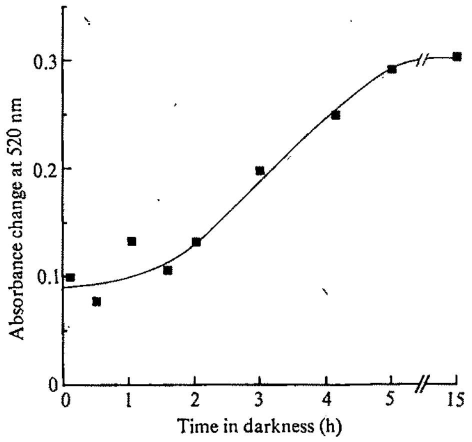

Fig. 2 Time course of porphyropsin regeneration in the retina of the living crucian carp. The ordinate refers to the amount of photosensitive material in extracts from six retinas, though two thirds of the data shown are based on double measurements with 2 × 6 retinas. Total number of experiments: fifteen.

This period, though shorter, is not of a different order of magnitude, however. Mammals, on the other hand, never show this lag[1]. Their regeneration curve begins with the rectilinear part which the fish retinas exhibit during the third and fourth hour of darkness when the pigment is re-synthesized at the rate of 14% of the bleached porphyropsin in 30 min. This figure means that the regeneration of porphyropsin *in vivo* is slow[6] and comparable with the regeneration of rhodopsin in cold blooded animals[9]. Three reactions are probably essential for the regeneration of the visual pigment: the formation of 3-dehydroretinal from the corresponding alcohol by oxidation, an isomerization of the retinal and the coupling of the prosthetic group with the protein. The first two reactions would involve two different enzymes—an alcohol dehydrogenase and an isomerase respectively. The course of consecutive enzymatic reactions is known to be complicated[10], and a curve like that in Fig. 2 could well result if the two enzymes were present in different concentrations and their respective Michaelis constants were also different.

This study was made while I was working with the MRC Vision Unit at the University of Sussex. The help of Professor Dartnall and the technical assistance of Mrs Erika Church are gratefully acknowledged.

L-Asparaginase and Complement

L-ASPARAGINASE, widely regarded as a potential oncolytic agent[1–6], is known to depress both cellular and humoral immunity. Our investigation of the effect of L-asparaginase on the complement system, described in what follows, reveals a more complicated interaction—the enzyme inhibits the complement in whole serum *in vitro* but is a potent activator of the same system in certain circumstances.

Human serum (1 ml.) was diluted five times and incubated for 2 h at 22° C with 50 U of L-asparaginase (LA). The enzyme was obtained from Merck, Sharpe and Dohme and was dialysed overnight against phosphate buffer (0.005 M) before use. The serum was then diluted a further ten times and its complement (C) activity was measured using 1×10^8 sheep erythrocytes sensitized with rabbit antibody (EA)[7]. The percentage haemolysis was determined kinetically by stopping the reaction with citrate–saline at intervals and measuring absorbance at 415 nm (Table 1). The same procedure was used in the case of guinea-pig serum except that it was diluted a further 200 times and readings were taken at shorter intervals (Table 2). Both human and guinea-pig sera have less C activity after treatment with LA; after 60 min, this effect is total and irreversible in human serum but partial and reversible in guinea-pig serum.

Table 1 Percentage Haemolysis obtained with Human Serum

LA added	Min of incubation			
(U)	10	30	50	60
None	3.3	45.0	62.0	67.0
50	0	0	0	0

Table 2 Percentage Haemolysis obtained with Guinea-pig Serum

LA added	Min of incubation		
(U)	7.5	10.5	18
None	39.5	81.0	95.0
50	5.0	36.0	80.0

In a second experiment, the intermediate EAC142 (ref. 8) was prepared by incubating 5×10^8 EA cells in 1 ml. with 0.25 ml. of human R3 for 2 min 30 s at 37° C. The cells were then incubated with ethylenediamine tetraacetate-treated guinea-pig serum (EDTA–serum) diluted thirty times, a reagent having the activity of the terminal C components from C3 to C9. After 25 min, the reaction was stopped by the addition of citrate–saline and the percentage haemolysis was determined by reading absorbance at 415 nm. The results were compared with those obtained with a similar intermediate prepared with an R3 reagent (diluted 1/15) that had been incubated for 15, 60 and 100 min at 22° C with varying amounts of LA (Table 3) before being mixed with EA cells. A significant inhibition of haemolysis occurred in the tubes containing the EAC142 intermediate prepared with an R3 pre-incubated with LA. Moreover, the inhibition seemed to depend on both dose and time.

Table 3 Percentage Haemolysis after Incubation of the R_3 Reagent

Asparaginase added to R_3	Min of incubation		
(U)	15	60	100
None	66.5	71.0	75.0
5	70.0	46.0	57.0
10	62.8	18.0	31.0
25	51.0	15.0	6.0
50	27.0	11.0	6.0

In the next experiment, guinea-pig serum was diluted five times and incubated with various quantities of LA. After incubation for 120 min EDTA was added to a final concentration of 0.01 M and the reagent was used to haemolyse EAC142 cells. From the data in Table 4, it can be concluded that LA has no influence on the terminal C factors C3 to C9.

It therefore seems that the inhibitory effect of LA on C takes place early in the sequence of C fixation, at the C1, C4 or C2 steps. Cells in the EAC1 state were prepared by incubating 1×10^8 EA cells with a suitable dilution of a C1 preparation for 10 min at 37° C[9]. The EAC1 intermediate was lysed by guinea-pig serum which had been diluted forty times and treated with Na_2 Mg-EDTA to permit the action of all the C components except C1. EAC1 was prepared in the same fashion, except that the C1 preparation was pre-incubated with 50, 25 and 10 units of LA during the 45 min before contact with EA (Table 5). Surprisingly, unlike the EA cells treated with native C1, the haemolysis of the EAC1 intermediate prepared with LA-treated C1 was greatly increased

Table 4 Percentage Haemolysis of EAC142 Intermediate

Asparaginase added to guinea-pig serum (before EDTA) (U)	% haemolysis
None	81.0
50	78.0
25	82.5
10	81.0

Table 5 Percentage Haemolysis of EAC1 Intermediate

LA added to C1 before contact with EA (U)	% haemolysis
None	25.9
50	31.0
25	59.5
10	67.0

after addition of Na_2 Mg-EDTA–serum. Moreover, the smaller the quantity of LA the greater the potentiation of haemolysis.

In other experiments, the use of cells in the EAC4 state enabled us to locate the LA action at the C1 stage. EAC4 cells were prepared after elution of C1 by EDTA from EAC14 cells[10]. To three tubes, one containing EAC4 (1×10^8 cells), one a suitable dilution of C1 and one a suitable dilution of C2, 75 U of LA was added. The tubes, together with tubes containing equivalent volumes of EAC14, C1 and C2 without LA, were incubated at 37° C for 60 min. From the pre-incubated samples, various mixtures of EAC4 and C1 were made and incubated for 20 min at 37° C (Table 6). C2 was added after centrifugation. The EAC142 so formed was centrifuged and incubated with guinea-pig serum diluted twenty-five times and treated with EDTA. The results confirm that LA produces its potentiating effect only in the presence of free C1. Whenever C1 is present in free form, LA behaves as a potent activator, the best results being observed with C1 which has been pre-incubated with LA (line 3 of Table 6). Moreover, fixed C4 is unaffected by LA-activated C1.

Table 6 Percentage Haemolysis by EDTA–Serum

Formation of the EAC142 intermediate*	% haemolysis
EAC4+C1+C2	10.3
EAC4LA+C1+C2	40.8
EAC4+C1LA+C2	51.8
EAC4+C1+C2LA	8.0

* The reagents pre-incubated with LA are designated EAC4LA, C1LA, C2LA.

At first glance, the results seem contradictory. Although LA inhibits C in whole serum, it behaves as a potent activator of the same system provided its action is limited to the first step in C fixation, that is, to the formation of cells in the EAC1 state. This can be explained, however, if one assumes that LA activates C1 with the subsequent formation of a potent C1 esterase. This, in turn, would cause an increased destruction of fluid phase C4 and C2[11,12] leading to a decrease in haemolysis in whole serum. On the other hand, when LA is incubated with C1 which is, after activation, used for the preparation of cells in the state EAC1, the intermediate produced shows a high reactivity. In this case, since the EAC1 cells are centrifuged before the addition of Na_2-mg-EDTA–serum, no free fluid-phase C1 esterase is present in significant amounts to inactivate C4 and C2. This situation is not unlike that in hereditary angioneurotic oedema[13], in which a decreased concentration of the inhibitor of C1 esterase results in an overactivity of the first component of C and a subsequent fluid phase destruction of C4 and C2.

The observations described here may well have their counterpart *in vivo*. They might, for example, give a clue to the severe anaphylactic reactions noted in some patients on administration of the drug[14]. An exploration of the behaviour of C in the blood of leukaemic patients treated with LA might throw some light on the mechanism of action of this enzyme and clarify the role of complement in therapeutic oncolysis. Moreover, human serum seems more sensitive to the action of LA than gp serum, a finding that is of course not unexpected.

Carboxymethylpachymaran, a New Water Soluble Polysaccharide with Marked Antitumour Activity

WE have reported that the polysaccharides lentinan[1,2] and pachymaran[3] strongly inhibit the growth of sarcoma 180 transplanted in mice, and that they could be considered as excellent immuno-accelerators of cell-mediated responses[4,5]. It is difficult, however, to dissolve them in water and to label them with isotopes, and their use in biological investigations can therefore be troublesome. We have now prepared a water soluble polysaccharide with marked antitumour activity, known as carboxymethylpachymaran ($[\alpha]_D^{20} = -2.8°$; $c = 1$ in H_2O; solubility, 6.7 g/100 ml. H_2O at 30° C) which can be labelled at the carboxymethyl residue with ^{14}C so that its distribution at the cellular and subcellular level can be investigated.

The results of the antitumour assays of carboxymethylpachymaran on sarcoma 180, Ehrlich carcinoma, MM-102 adenocarcinoma[6], CCM carcinoma[7] and NTF lymphosarcoma[8] are shown in Tables 1 and 2.

Antitumour activity was measured by the method described before[2]. A 7 day old ascites tumour was transplanted subcutaneously into the right groin of a mouse. This produced solid tumours at the site of inoculation. Carboxymethylpachymaran was injected intraperitoneally every day for 10 days starting 24 h after tumour transplantation. In assays terminating at the end of 5 weeks, the mice were killed and the tumours were removed and weighed. Tumour inhibition ratios were calculated by comparing the experimental and control mice. The antitumour effects of carboxymethylpachymaran on sarcoma 180 and MM-102 adenocarcinoma were striking, for the tumours regressed completely in many mice. Any direct action of the polysaccharide against tumour cells similar to that manifested by lentinan was not observed, and whereas pretreatment with lentinan[5] 14–45 days before

Carboxymethylpachymaran was injected intraperitoneally in every case. The vehicle was distilled water.

tumour transplantation produced a marked effect, pretreatment with carboxymethylpachymaran at this time was ineffective. On the other hand, carboxymethylpachymaran had a pronounced antitumour effect which was, except for oral administration, irrespective of injection route, whereas lentinan was effective only after intraperitoneal injection.

Carboxymethylpachymaran was synthesized from pachymaran[3], a β-(1→3)linear glucan. A suspension of 3 g of pachymaran in 80 ml. isopropanol was mixed with 8 ml. of 30% aqueous sodium hydroxide, and stirred vigorously. Monochloroacetic acid (3.6 g) was then added to the mixture and the reaction was continued for 2 h at 40°–50° C with stirring. The reaction product, carboxymethylpachymaran, was filtered in suction and washed with 70% methanol–acetic acid solution, 80% aqueous methanol, 100% methanol and acetone, successively, and dried *in vacuo*; the yield was 3.3 g. The degree of carboxymethyl substitution in the polysaccharide thus prepared was 0.95 mol per anhydrous glucose unit. ^{14}C-Labelled carboxymethylpachymaran could be obtained by incorporating monochloroacetic acid labelled with ^{14}C in the mixture.

The studies of the mechanisms of action of antitumour polysaccharides on organ, cellular and subcellular level are in progress using the ^{14}C-labelled carboxymethylpachymaran. Carboxymethylpachymaran with lentinan is worth considering as a useful agent in cancer research and cellular immunology.

We thank Dr W. Nakahara and Dr F. Fukuoka for their continued interest and Misses Y. Arai and M. Noda for their cooperation.

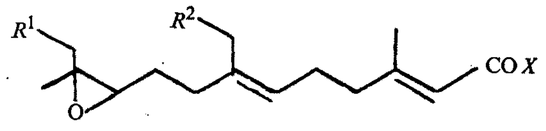
Terpenoid Amines as Insect Juvenile Hormones

After the discovery that an epoxide derivative of farnesenate esters (1) showed high juvenile hormone (JH) activity[1], we undertook to synthesize related compounds in an effort to find the most potent of this class of materials. The elucidation of the structure of two hormones from *Hyalophora cecropia* (2 (ref. 2) and 3 (ref. 3)) as homologues of the farnesenate structure, and the observation that products obtained from the addition of hydrogen chloride to farnesenate esters (18) also possessed hormone activity[4], led to the inclusion of analogous compounds in our programme. Here we describe results with a series of amide derivatives.



1, $R^1=R^2=H$, $X=OCH_3$

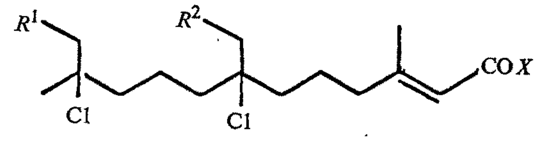
2, $R^1=R^2=CH^3$, $X=OCH_3$

3, $R^1=CH_3$, $R^2=H$, $X=OCH_3$

4–10, $R^1=R^2=H$, $X=NHR^3$

11, $R^1=R^2=CH_3$, $X=NHR^3$

12–17, $R^1=R^2=H$, $X=N(R^3)_2$



18, $R^1=R^2=H$, $X=OC_2H_5$

19, $R^1=R^2=H$, $X=NHR^3$

20, $R^1=R^2=H$, $X=N(R^3)_2$

21, $R^1=R^2=H$, $X=NHR^3$

The method used for the preparation of compounds (5) to (17) involved the phosphonate modification of the Wittig reaction[5]. Condensation of the appropriate N-substituted diethyl carbamoylphosphonate with geranylacetone, using sodium hydride as the condensing agent, gave the olefinic precursors to compounds (5)–(10) and (12)–(17). The precursor to compound (11) was obtained by a similar reaction with 6-ethyl-10-methyl-5,9-dodecadien-2-one[6]. Preparation of the intermediate N-substituted diethyl carbamoylmethylphosphonates involved treating chloroacetyl chloride with the appropriate amine to give N-substituted chloroacetamides, followed by a Michaelis–Arbuzov reaction with triethyl phosphite[7]. The precursor to the unsubstituted amide (4) was prepared by hydrolysis of the corresponding nitrile, obtained in turn from geranylacetone and diethyl cyanomethylphosphonate[8]. Epoxidations were carried out with *m*-chloroperbenzoic acid in methylene chloride, and the products were purified by chromatography on silica gel.

The dichloro derivatives (19–21) were prepared by adding hydrogen chloride to farnesenic acid or 7-ethyl-3,11-dimethyl-2,6,10-tridecatrienoic acid, followed by conversion to the acid chloride with thionyl chloride[9] and treatment with the appropriate amine. Attempts to prepare the dichloro derivatives of the amides by adding hydrogen chloride to the corresponding olefinic compounds were unsuccessful. All compounds prepared for this study were fully characterized by elemental analysis and by nuclear magnetic resonance and infrared spectrometry.

Table 1 Juvenile Hormone Activity of Terpenoid Amide Derivatives on *Tenebrio molitor*

Compound No.	R^3	Minimum active dose (μg)	% response

21	C_2H_5	0.1	43

Activity is minimum dose per pupa required for retention of significant pupal characteristics (equivalent to a "3" on the numerical scale of Bowers and Thompson[10]). Compounds are mixtures of all possible isomers except (19a) and (20a).

Initial screening for JH activity was carried out using freshly moulted pupae (10–20 h) of the yellow mealworm, *Tenebrio molitor*[10]. Twenty insects were used at each dose level, and minimum active doses were confirmed by three replicates. The substances were applied topically in 1 μl. of a solvent comprising 9 parts acetone and 1 part oily vehicle, usually squalene.

The presence of the oil in the topical formulations has been found to enhance the activity of many JH agents. This is particularly true of the dichloro derivatives (19–21); in the absence of the oil, these substances were active only at 100 to 1,000-fold larger concentrations. The nature of the oil was also found to be important. In general, oils with high unsaturation gave better results: exceptions were coconut oil and squalane, essentially saturated substances which afforded significant potentiation.

Of the epoxides (5–17), the N-ethyl derivatives (6) and (11) are by far the most potent of the series, and are the most potent in the *Tenebrio* screen of any published JH substances. By comparison, a synthetic mixture of isomers of *Cecropia* JH[6] had an activity of 0.1 μg, and 6,7-epoxy-3-ethyl-7-methyl-2-nonenyl-3,4-methylenedioxyphenyl ether[11] had an activity of 10^{-3} μg in the same assay procedure. Among the monoalkyl amides the JH activity falls off rapidly with decreasing and increasing size of the N-substituent. Among the dialkylamides both (13) and (16) show significant activity, but do not approach the potency of (6).

Synthesis of the dichloro derivatives (19) and (20) facilitated the isolation of pure *trans* isomers (19a) and (20a). It is interesting to note that in both cases the mixtures (19) and (20) are 100-fold more active than the corresponding *trans* isomers. The mixtures were characterized by nuclear magnetic resonance spectrometry, and were shown to be predominantly the *cis* and *trans* isomers of 7,11-dichloro-7,11-dimethyl-2-dodecenamides. Impurities were detected, however, and they could account for the enhanced activity. The *Cecropia* JH analogue (21) is much less active than the farnesenamide (19); the former is a much more complex mixture of isomers, and has not been as well characterized as (19).

The N-ethyl amides are structually very similar to the esters (1–3). Increased potencies could well be due to the different binding characteristics of the secondary nitrogen (both an electron pair and a hydrogen atom for noncovalent interactions) or to increased stability of the amide over the ester group. The only other nitrogen containing compounds with JH activity are some carbamates reported by Schwarz *et al.*[8] and some peptide derivatives reported by Zaoral and Sláma[12].

During our screening programme combinations of JH agents, or JH agents and insecticide synergists, were examined. In most cases there was little, if any, enhancement of activity, but a 1 : 1 combination of (6) and (19) produced a remarkable potentiation in the *Tenebrio* assay. Pupal characteristics were retained by the test insects at doses as low as 10^{-6} μg.

Compound (6) is effective in preventing maturation of houseflies (*Musca domestica*) when applied topically to final instar larvae. No normal adults are obtained at doses of 0.01 μg. Compound (19) was less active, affording complete control at 0.1 μg per larvae. Only slight potentiation effects are observed on houseflies with combinations of (6) and (19). Adult mosquitoes (*Culex pipiens*) fail to emerge from pupae when larvae are reared in water containing 0.1 p.p.m. of (6).

Incorporation of either (6) or (19) into the diet of the German cockroach (*Blatella germanica*) effectively controls colony growth and most of the adults die within a few days of being given a bait of starch containing 20 p.p.m. of the active ingredient. Gravid females drop their egg sacs prematurely, and the hatch, if any, is very small. Any nymphs which appear fail to survive to adulthood. The baits have retained their effectiveness for more than 6 months against exposure in a test cage.

Although this effect on cockroaches seems to be a general toxic response, it is also highly specific to this species. Other species, such as *Tenebrio molitor* and *Triboloium confusum*, survive as larvae or adults in media containing up to 100 p.p.m. of either (6) or (19). Development of the larvae is arrested (larvae ultimately die long after pupation would normally have occurred) and eggs laid by the adults fail to develop, but no "toxic" deaths are observed. Other species such as the Indian meal moth (*Plodia interpunctella*) seem to be unaffected by either compound. One can only speculate that the *Corpora allata* hormone(s) have some metabolic function in adult insects, and that the German cockroach is particularly susceptible to disruption of this function.

Acute oral toxicity tests have been carried out with both (6) and (19). Massive doses of (6) (3,200 mg/kg) are without effect on laboratory mice. Compound (19) has an observed LD$_{50}$ of 3,980 mg/kg, a value which indicates this material is relatively safe as far as acute toxicity is concerned.

We thank Mrs E. O. Johnson and Mr D. S. Pincus for technical assistance.

Possible Role of the Pituitary/Adrenocortical Axis in Aggressive Behaviour

THE recent finding by Cherkin and Meinecke[1] that aggressive behaviour in previously isolated male rabbits could be suppressed for some weeks by allowing them to recover in pairs from barbiturate anaesthesia, raises an interesting question concerning the action of components of the pituitary/adrenocortical axis on behavioural responses. It is well established that most forms of anaesthesia are "stressful" in that they result in activation of the adrenal cortex, and the possibility thus exists that findings such as those by Cherkin and Meinecke are a consequence of changes in ACTH.

The role of pituitary and adrenocortical hormones on behaviour has been recently reviewed by Levine[2], and evidence has been obtained that ACTH depresses isolation-induced aggressive behaviour in the albino mouse[3,4].

Defeated animals show a pronounced increase in adrenocortical activity[5–7] which is not evident in the victor and it seems likely that this increase in ACTH and/or glucocorticoids may have a cue function in inducing subordinate behaviour by increasing the fear response and reducing the aggressive response. An alternative explanation for the result obtained by Cherkin and Meinecke is thus that the stress of anaesthesia causes both animals to assume subordination on emerging from anaesthesia with a consequent suppression of aggressive behaviour. This subordination could be specific to the animal in whose presence they recovered: dominance could be associated with the visual or olfactory characteristics of the other animal.

I thank Professor Chester Jones for encouragement and the SRC for a fellowship.

Myoid Conduction in the Siphonophore *Nanomia bijuga*

Myoid conduction has been suspected in the Cnidaria for some sixty years[1], but has only recently been demonstrated[2,3]. There are no recordings available of activity at the cellular level; until now potentials from cnidarian muscles have been recorded with large extracellular electrodes covering a number of active units.

The stem of the siphonophore *Nanomia bijuga* is covered with a layer of epithelio-muscular cells some 45 µm thick (Fig. 1); this is far thicker than similar cells in many other cnidarians. The muscle fibrils run longitudinally and are non-striated.

Portions of the stem, about 4 cm long, were pinned onto the wax base of a cooled chamber and covered with seawater maintained at 13° C. Cells were successfully impaled by glass microelectrodes filled with 2.8 M potassium chloride having resistances of between 60 and 80 MΩ. Resting potentials of between −50 mV and −80 mV were obtained with 63 mV being the mean of twenty penetrations. This value is in agreement with the values given for anthomedusan epithelia[3]. Many preparations showed spontaneous activity with cell interiors depolarizing 17–20 mV (Fig. 2). The rise time of these potentials is approximately 10 ms, but repolarization takes up to 3 s. These events were conducted without decrement along 2 cm of the stem with a conduction velocity of 20 cm/s as measured by a pair of extracellular suction electrodes.

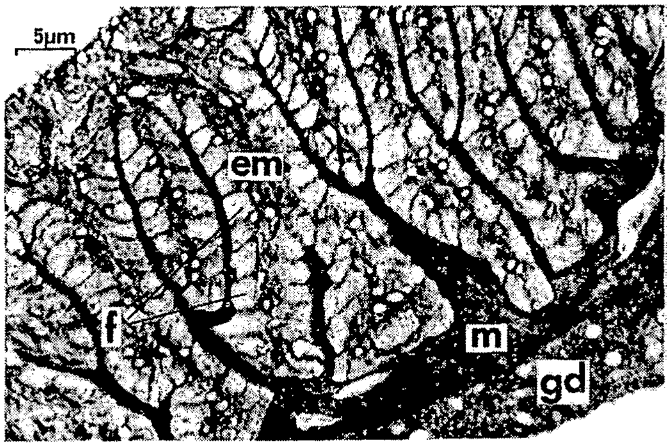

Fig. 1 Transverse section of stem of *Nanomia*, 0.5 µm 'Epon' section (Richardson's stain); em, single layer of epithelio-muscular cells; f, fibrils of epithelio-muscular cells; gd, gastrodermis; m, mesogloea.

If the preparation was shocked by square wave pulses of 1 ms duration delivered by a suction electrode to the surface of the stem two distinct types of potential changes were seen in the conducting cells. The type of potential change was dependent on stimulus strength.

The electrical constants of this preparation were not known, and so the exact current delivered below the stimulating electrode could not be calculated. With the distance between the microelectrode and the stimulating electrode at 1 cm, shocks delivered at a potential of 3 V gave no change in the potential of the cell interior (Fig. 2). At 4 V there is a distinct depolarization of the cell membrane and at 6 V an even greater change so that the interior of the cell became 4 mV more positive. In such cases the rate of increase of positive charge inside the cells is very slow. Events such as these which I have called sub-threshold pulses are not propagated but are probably conducted with decrement. At a specific stimulus strength (about 9.5 V) for any one preparation the penetrated cell will fire giving a rapid decrease in the potential across the outer membrane of the cell. This event I have called a supra-threshold pulse and it seems to be identical to the spontaneous pulses already described.

Each supra-threshold pulse causes a slight contraction of the longitudinal muscle fibres, often sufficient to dislodge the microelectrode. Contractions during spontaneous firing never caused the microelectrode to come out of the cell. If a micro-

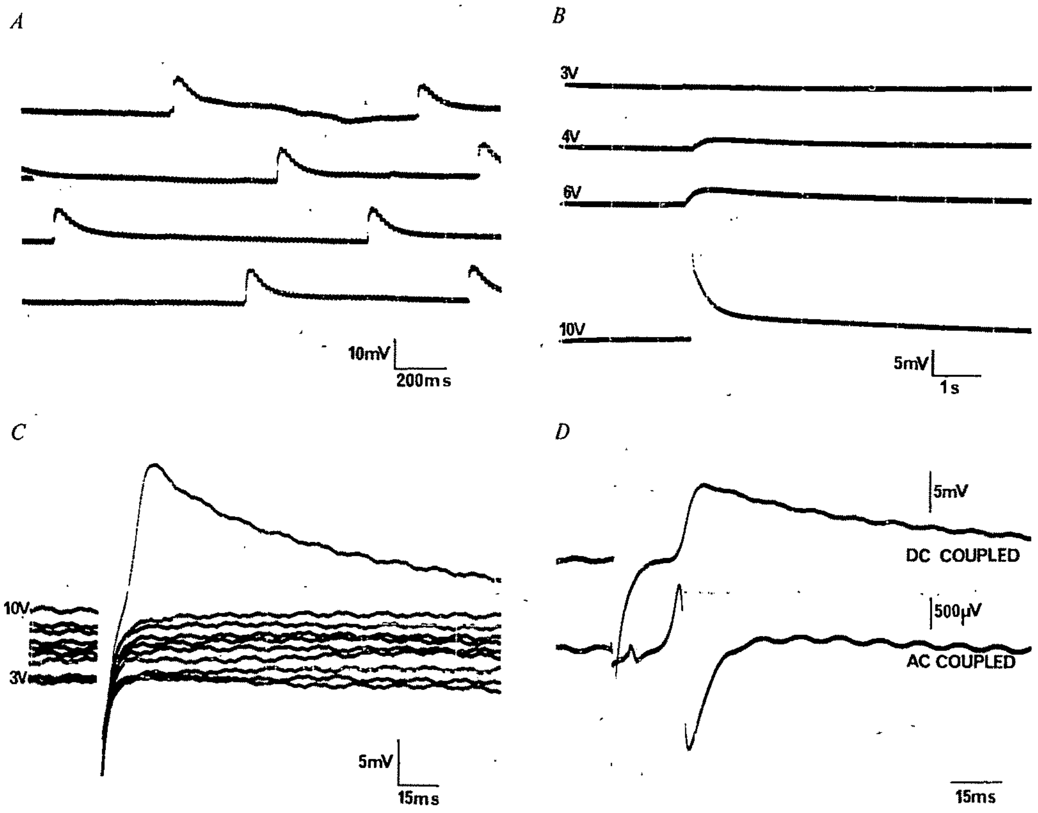

Fig. 2 *A*, Spontaneous supra-threshold pulses; *B*, electrically stimulated pulses showing change from sub-threshold pulses to a supra-threshold pulse as stimulus strength is increased; *C*, same as *B* but tracings superimposed; *D*, a stimulated supra-threshold pulse as recorded by an intracellular electrode (upper trace), and an extracellular suction electrode above the intracellular electrode (lower trace).

electrode is placed directly beneath a suction electrode one can compare the passage of a supra-threshold pulse as recorded inside and outside the cell. The suction electrode in this case is covering more than one cell. The wave-shape and duration of this pulse, as recorded by the extracellular electrode, are very similar to those recorded from other hydrozoan epithelia[3–5].

Procion yellow and Niagara sky blue 6B injected iontophoretically diffused through a number of cells and so failed to show the exact location of the electrode tip. Use of a screw-micrometer to advance the electrode indicated that the tip in most cases would have been in or just above the muscle fibrils.

The preparation continued to propagate supra-threshold pulses when immersed in a solution containing one part sea-water and one part isotonic magnesium chloride. Excess Mg^{2+} blocks nervous activity in other hydrozoans, so it seems that propagation of supra-threshold pulses does not depend on the nerve-net[3].

It is not yet possible to prove that these recordings are intracellular—they could conceivably be transepithelial pulses. Such pulses have been recorded between the enteron and surrounding water in *Hydra* but they have the opposite polarity to the pulses recorded in *Nanomia*[6]. If they are intracellular recordings then one might suppose that the cells in this conducting epithelium are connected by low resistance pathways as demonstrated by the local spread of sub-threshold excitation. This is a reasonable hypothesis since similar types of junctions have already been proposed for conducting epithelia and smooth muscles[7–9].

I thank G. O. Mackie for his help. This study was assisted by an operating grant to G. O. Mackie from the National Research Council of Canada. I am the recipient of a National Research Council (Canada) graduate scholarship.

Corrosion by the Sulphate-reducing Bacteria

THERE are several explanations for the aggravation of corrosion of iron and steel in oxygen-free conditions by sulphate-reducing bacteria. These are (*a*) stimulation of the cathodic part of the corrosion cell by the removal and utilization of the polarizing hydrogen by the bacteria[1]; (*b*) stimulation of the cathodic reaction by solid ferrous sulphides formed by the reaction of ferrous ions with sulphide ions produced by bacteria[2]; (*c*) stimulation of the anodic reaction, metal dissolution, by bacterially produced sulphide[3]; (*d*) local acid cell formation[4], and (*e*) formation of iron phosphide by reaction of the metal with bacterially reduced phosphates[5].

There is little evidence that (*d*) and (*e*) are significant except possibly in isolated cases, whereas (*c*) is probably important only at the start of the corrosion process due to the eventual formation of protective sulphide films in the presence of free sulphide ion[6].

Much support for (*a*), the cathodic depolarization mechanism first postulated by von Wolzogen Kühr, has come from work by Booth and Tiller[7]. Using mild steel electrodes at various controlled potentials, they observed a straight line relationship between the hydrogenase activity of the bacteria and the extra current required to maintain these potentials on the cathodes in the presence of resting-cell suspensions of sulphate-reducing bacteria, provided with benzyl viologen as electron acceptor. But the organisms used had been cultured on standard sulphate-containing medium and the resting-cell suspensions would therefore contain ferrous sulphide, both free and embedded in the mucopeptide material adhering to the cells. (The ferrous sulphide that forms during growth in sulphate media is impossible to separate completely from the bacteria except by chemical methods so severe that the bacteria themselves are destroyed.)

Using the same procedure as Booth and Tiller[7], we have observed a direct relation between the amount of chemically prepared ferrous sulphide added to a bacteria-free system, and the extra current required, as previously described. Moreover, organisms previously grown in a sulphate-free fumarate medium[8] showed little cathodic depolarization. This latter result could explain the low weight loss/time results obtained by Booth, Elford and Wakerley[2] with mild steel coupons in semicontinuous cultures of the bacteria in a sulphate-free fumarate medium. The similarity between the results of their potentiostatic experiments and those obtained by Booth and Tiller[7] suggests that there is some connexion between the rate of bacterial hydrogen uptake and the amount of ferrous sulphide present (this possibility was adumbrated by the observation of Goldner *et al.*[9] that particulate material stimulated hydrogen uptake). We have now confirmed this, using Warburg manometry to measure the rate of hydrogen uptake by bacteria grown on both sulphate-free and sulphate-containing media. When chemically prepared ferrous sulphide was added to the resting cell suspensions in the reaction flasks, substantially greater rates of hydrogen uptake were observed in nearly every case, using either sulphate or benzyl viologen as electron acceptor (Table 1).

This effect of ferrous sulphide may explain the wide variation encountered in manometric determinations of $-Q_{H_2}$ for the sulphate-reducing bacteria[10], since variable amounts of ferrous sulphide are carried over into the reaction flasks as is easily verifiable visually; the effect may also have a bearing on the observation[11] of a small hydrogen uptake by *Desulfotomaculum orientis*, a sulphate reducer usually considered to be hydrogenase-negative, and this question is being studied further.

Ferrous sulphide alone, though known to be cathodic to mild steel[2,12], is not a permanent cathode. Our weight loss/time experiments indicate that chemically or bacterially produced ferrous sulphides corrode by a first order reaction and that the eventual total corrosion is directly proportional to the

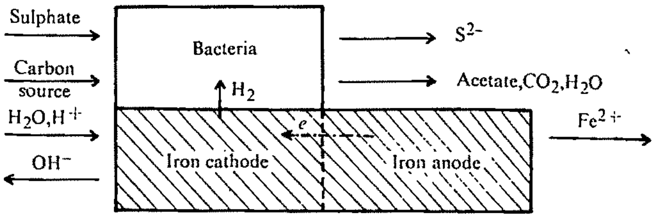

Fig. 1 Scheme illustrating the classic theory of cathodic depolarization by the sulphate-reducing bacteria.

* Bacteria were suspended in 0.04 M phosphate buffer (*p*H 7.0) for manometry.

† Additions of ferrous ion (as $FeCl_2$) or sulphide ion (as Na_2S) alone did not increase the hydrogen uptake rate. Ferrous sulphide was inactive towards hydrogen for additions of sulphate or benzyl viologen in absence of the bacteria.

amount of ferrous sulphide present. Sustained high corrosion rates in such bacteria-free systems are only obtained by continual replenishment of the ferrous sulphide such as occurs in cultures in iron-rich medium where all the sulphide or bisulphide ion produced by bacterial metabolism is precipitated as ferrous sulphide[13]. In media containing minimal iron, free sulphide ions cause the formation of sulphide films which confer fair protection to the metal underneath. These films are not permanent, however, and the time for breakdown to occur is probably linked to the activity of the bacteria[13]. High rates of corrosion are observed once film breakdown occurs. It seems that once there is sufficient ferrous sulphide present to initiate the formation of the galvanic cell ferrous sulphide|Fe, then a high corrosion rate is attained and no sulphide films are formed. An observation that steel coupons in semicontinuous cultures of sulphate-reducing bacteria, grown initially on iron-rich and later on minimal-iron media, exhibit continued high corrosion rates supports this view (personal communication from D. S. Wakerley).

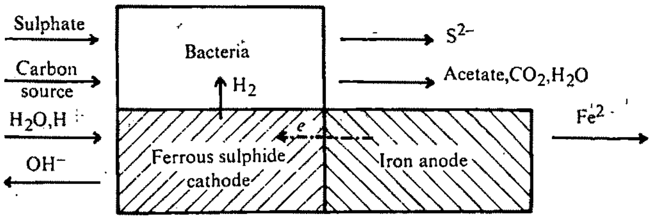

Fig. 2 Scheme illustrating the proposed mechanism of corrosion by the sulphate-reducing bacteria.

The presently accepted theory of corrosion by cathodic depolarization is represented diagrammatically in Fig. 1. We propose a new theory of corrosion by the sulphate-reducing bacteria such that the cathodic reaction, hydrogen evolution, occurs on the ferrous sulphide produced by reaction of ferrous ion with bacterially produced sulphide ion. We find that the ferrous sulphide activity is diminished with time, possibly owing to the bonding of atomic hydrogen within the ferrous sulphide crystals; but the activity of the sulphide is restored by removal of the atomic hydrogen by bacterial hydrogenase activity. This mechanism is illustrated schematically in Fig. 2.

Infection of Schistosomes with Gram-positive Cocci

Schistosoma spindale (Montgomery) is a common trematode parasite of cattle, water buffalo, goats and other mammals over a vast area including southern Africa, South and South-East Asia. It is a close relative of the human parasite *S. haematobium* and while it has only rarely been reported from man it is a significant producer of cercarial dermatitis in rice field workers. As part of an investigation of *S. spindale* in Malaysia, a number of laboratory animals were infected in various ways with cercariae of this helminth. One young female white mouse was exposed by tail immersion to numerous cercariae of a local strain in Kuala Lumpur and killed 82 days later with 0.3 ml. of heparinized 'Nembutal' (pentobarbital sodium) injected intraperitoneally. The liver and spleen were larger than those usually found in mice with *S. spindale* infections of similar age. The spleen was soft and yellowish-white and particularly distended over about half its length. Small pieces of liver, spleen, lungs and intestine were fixed in 10% formalin, after which the mouse was perfused with citrated saline according to the method of Duvall and DeWitt[1]. Eighteen pairs of worms and thirty adult males were recovered in the perfusate; all except one pair and two males had nodular lesions (Fig. 1 *b–f*) visible to the naked eye or with low magnification. I found several additional worms, including some with such lesions, in the tissues (Fig. 1*f*), but no affected worms in fifty-seven other mice similarly exposed and perfused. The discovery of these diseased worms was unanticipated. Because their significance was not immediately appreciated, they were fixed with 10% formalin and stored in 70% alcohol as usual. On subsequent examination, it became clear that their nodular lesions were filled with great

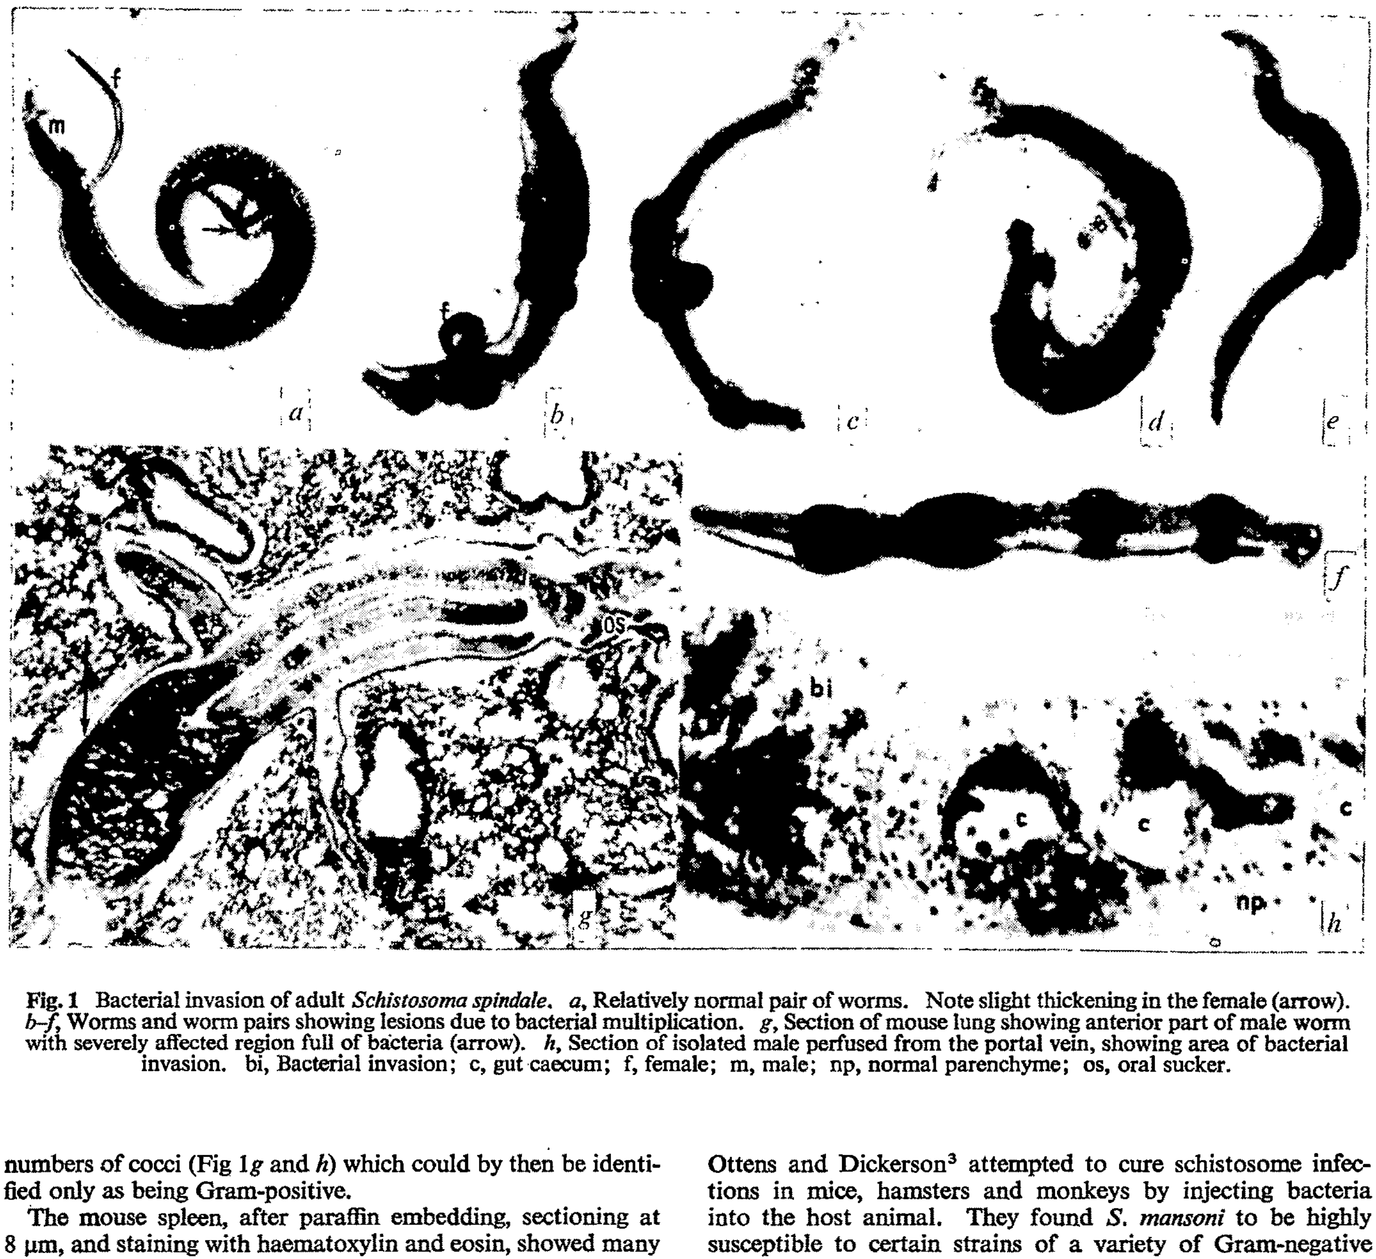

Fig. 1 Bacterial invasion of adult *Schistosoma spindale*. *a*, Relatively normal pair of worms. Note slight thickening in the female (arrow). *b–f*, Worms and worm pairs showing lesions due to bacterial multiplication. *g*, Section of mouse lung showing anterior part of male worm with severely affected region full of bacteria (arrow). *h*, Section of isolated male perfused from the portal vein, showing area of bacterial invasion. bi, Bacterial invasion; c, gut caecum; f, female; m, male; np, normal parenchyme; os, oral sucker.

numbers of cocci (Fig 1*g* and *h*) which could by then be identified only as being Gram-positive.

The mouse spleen, after paraffin embedding, sectioning at 8 µm, and staining with haematoxylin and eosin, showed many clumps of cocci in the centre of the expanded whitish region in areas of necrosis and intense cellular activity. Many polymorphonuclear leucocytes were present, together with macrophages containing phagocytosed bacteria. Numerous fibroblasts were seen in and around the region. The condition was consistent with acute splenitis of several days' duration. Bacterial invasion of the spleen was perhaps facilitated because that organ was already compromised owing to portal hypertension induced by the schistosome infection. In the liver, a small area of bacterial invasion surrounded the remains of a worm whose caeca contained masses of bacteria.

It is likely that bacteriaemia in the mouse led to infection of the schistosomes. The worms, which dwell in the intestinal and portal venous systems, had probably ingested bacteria along with their usual diet of blood. Sections and stained whole mounts of worms show that multiplication of bacteria occurs primarily in the gut caeca, which become greatly dilated; the parenchyma is then subject to massive invasion (Fig. 1*h*). The worms, in turn, act as amplifiers of the bacterial infection and serve as intense focal sources of organisms for potential invasion of adjacent tissues. Krakower *et al.*[2] found that Puerto Rican *S. mansoni* in some rats deficient in vitamin A were invaded by Gram-positive bacilli such as *Lactobacillus acidophilus*, a normal gut inhabitant presumed to have passed through the intestinal wall as a result of the malnutrition. Ottens and Dickerson[3] attempted to cure schistosome infections in mice, hamsters and monkeys by injecting bacteria into the host animal. They found *S. mansoni* to be highly susceptible to certain strains of a variety of Gram-negative bacilli and also observed bacterial invasion and lethal effects in *S. mattheei*, a member of the "haematobium" group to which *S. spindale* also belongs. These authors, moreover, evaluated twenty-four strains of Gram-positive bacteria (not specified), none of which invaded schistosomes.

This report is the first to demonstrate that Gram-positive cocci may be highly invasive and pathogenic in adult schistosome worms.

This work was done in part when I was a staff member of the University of California ICMRT at the Institute for Medical Research, Kuala Lumpur, Malaysia; supported by a US Public Health Service grant. I thank Drs S. DeWitt and K. Vosti of Stanford University for their comments.

Temperature Optimum of Non-sulphur Bacteria from a Spring at 90° C

It is well established that bacteria live in hot springs at temperatures greater than 90° C depending on altitude[1-4]. We have studied the physiology and temperature optima of these organisms by growing them on coverslips and measuring directly the uptake of various radioactively labelled compounds[5]. The bacteria were obtained from an unnamed spring, known to us as "pool A", which is in the Lower Geyser Basin of Yellowstone National Park[4], and which has a temperature of 90°–91.5° C and is therefore just below the boiling point for this altitude. It has a pH of 8.6–8.9 and a low sulphide content (0.096 µg/ml.). Our work on Boulder Spring, a superheated spring with a relatively large sulphide content (3.1 µg/ml.), revealed that the bacteria in that spring incorporated radioactively labelled compounds only when sulphide was present[6], yet the uptake by bacteria from pool A was inhibited by sulphide.

Bacteria from pool A incorporated radioactive amino-acids, thymidine and lactate, but incorporation of labelled sugars was negligible. Detailed studies with radioactive leucine (Table 1) showed that isotope uptake was inhibited not only by formaldehyde but also by streptomycin, novobiocin, sodium azide, Na_2S and mercuric bichloride. Uptake of radioactive leucine is also inhibited by non-radioactive leucine and by yeast extract. It is clear, therefore, that isotope uptake is due to a vital process and not to passive uptake or adsorption. Attempts to stimulate uptake of leucine, acetate or bicarbonate by bubbling with methane, nitrogen, CO_2 or air during the incubation period were unsuccessful.

Table 1 Effect of Inhibitors on Uptake of ^{14}C-Leucine by Bacteria from Pool A

Conditions	c.p.m./coverslip
Control	4,622
+HCHO (4%)	364
+streptomycin (1,000 µg/ml.)	429
+$HgCl_2$ (100 µg/ml.)	317
+NaN_3 (1,000 µg/ml.)	153
+novobiocin (100 µg/ml.)	100
+Na_2S (150 µg/ml.)	998
+Na_2S (15 µg/ml.)	2,234
+yeast extract (0.1%)	35
+non-radioactive leucine (1,000 µg/ml.)	87

Incubation at 86° C for 1 h in synthetic D medium[8] at pH 7.0 with 0.06 µCi/ml. ^{14}C-leucine.

The optimum pH for uptake of leucine was between 7 and 7.5 (Fig. 1) irrespective of whether spring water or synthetic salts adjusted to various pH values were used. In determination of the temperature optimum at pool A, both spring water at its natural pH and synthetic salt solution at pH 7 were used as incubation media. Although the amount of isotope uptake was much greater in the latter, the temperature optima for both media were the same. A number of experiments were done to determine the temperature optimum for the incorporation of different labelled compounds. Fig. 1 shows results of a single experiment in which five compounds were run in parallel. Only 5–10 min equilibration at the various temperatures was allowed, so that there was no possibility of adaptation to the new temperatures. We assume therefore that the optima represent those which the bacteria had in the spring itself. The optima for all compounds are virtually the same, 90° C. In other experiments, optima ranging from 86° to 90° C were found. During the past 6 yr we have measured the source temperature of pool A many times and have found that it ranges from 90.5°–91.5° C. Thus the temperature optimum of these bacteria is virtually identical to their environmental temperature.

These data and those from Boulder Spring[6] suggest that these bacteria are optimally adapted to the temperatures of the springs. It would be interesting to know the temperature optima of the bacteria living in the boiling springs of New Zealand[7], which have temperatures of 99°–100° C. Clearly the bacteria found in Yellowstone springs at 90° C should not be able to multiply in the New Zealand springs.

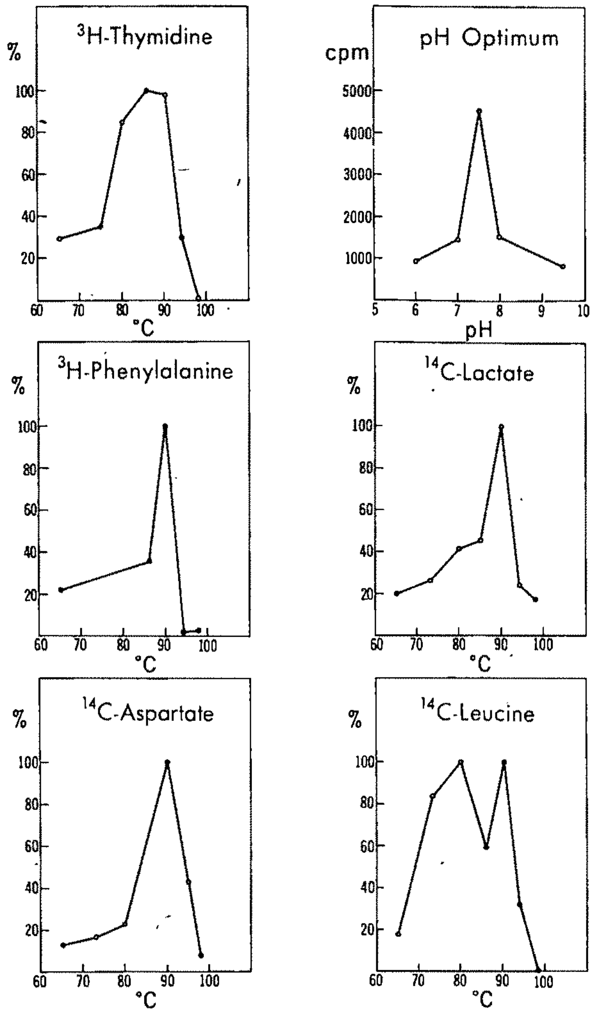

Fig. 1 Temperature and pH optima for the bacteria of pool A. Upper right, pH optimum for the uptake of ^{14}C-leucine. Incubation was at 86° C for 1 h with 0.06 µCi/ml. ^{14}C-leucine. pH values were obtained by adjusting the spring water with 1 M HCl or 1 M NaOH. Other graphs, temperature optima for the uptake of several labelled compounds, all at 0.06 µCi/ml. The results are plotted as percentage of maximum incorporation for each isotope. The 100% values in c.p.m./coverslip were as follows: ^{3}H-thymidine, 492; ^{3}H-phenylalanine, 2,224; ^{14}C-aspartic, 840; ^{14}C-lactate, 92; ^{14}C-leucine, 11,545. Specific activities of the various radioactive compounds are as follows: thymidine, 0.25 mCi/0.00368 mg; phenylalanine, 1 mCi/0.067 mg; aspartic, 3.65 mCi/mmol; lactate, 0.1 mCi/2 mg; leucine, 0.05 mCi/0.025 mg. Incubation in synthetic D medium[8], pH 7. Temperatures over boiling (92.5° C) were obtained using boiling water baths with saturated $MgSO_4$.

Potential Cocarcinogenicity of Sodium Hypochlorite

SODIUM hypochlorite has been widely used as a bleaching agent and disinfectant. No particular hazard of this chemical to man has been recognized (see, for example, ref. 1) except for the poisoning of infants by the accidental ingestion of concentrated solution. We now report, however, that sodium hypochlorite is definitely concerned in cancer production in mice as a cocarcinogen[2-4].

In testing for cocarcinogenicity, a group of animals is treated with a potent carcinogen in a dose which by itself is not enough to produce a cancer. A suspected chemical cocarcinogen is also given to the same animals, either before or after. The development of a cancer offers a sensitive test for potentially carcinogenic compounds[5-7].

A commercial sodium hypochlorite solution which contained more than 10% effective chlorine was used. The carcinogen selected was 4-nitroquinoline 1-oxide[8,9]. The mice were ddN strain females maintained on water and a standard pellet diet. Before the application of the chemicals, hair was clipped off over an area 1 cm in diameter in the interscapular region where the chemicals were applied.

Three groups of forty 5 week old mice were used. One group was used in a combination experiment.

Twenty applications of 4-nitroquinoline 1-oxide alone produced neither malignant nor benign tumours. Although hypochlorite did not induce skin tumours by itself in sixty applications, skin tumours were induced in nine of thirty-two mice by forty-five applications given after submanifestational doses of 4-nitroquinoline 1-oxide. Thus, one fibrosarcoma of the skin and three squamous cell carcinomas were produced after about 240 days. Five papillomas remained until the end of the experiment. In one tumour-bearing mouse metastases to lung and kidney were observed. Besides the skin tumours, one lymphatic leukaemia was found in another mouse about 360 days after the start of the experiment. No tumours resulted from sixty paintings of aqueous sodium hydroxide at *p*H 11 ~12 combined with twenty applications of 4-nitroquinoline 1-oxide, indicating that potential carcinogenicity of hypochlorite solution is due to the hypochlorite itself and not to the alkalinity of the solution.

Solutions of sodium hypochlorite containing approximately 5% chlorine are available commercially and used widely. For bleaching, the solution is diluted up to several hundred times. Various materials, including foods, may be sterilized using a solution diluted several hundred times. Drinking water may be disinfected by a low concentration of chlorine (0.1 to several parts per million). In the treatment of some skin diseases caused by fungi, a dilute solution may be applied directly to the diseased part. Although in such conditions it seems unlikely that this common chemical constitutes a practical carcinogenic hazard, the data presented here provide a caution against its indiscriminate use.

We thank Dr W. Nakahara, director of the National Cancer Center Research Institute, for valuable discussion and pathological diagnosis and Professor T. Ukita of the Faculty of Pharmaceutical Sciences, University of Tokyo, and Dr F. Fukuoka of the National Cancer Center Research Institute for research facilities.

Table 1 Carcinogenicity of Sodium Hypochlorite in Mice when Combined with a Submanifestational Dose of Carcinogenic 4-Nitroquinoline 1-Oxide

	No. of mice	Skin tumours Malignant	Skin tumours Benign	Leukaemia
		(No. of mice)		
Group 1	32	4	5 (1)	1
Group 2	29	0	0	0
Controls	27	0	0	0

The potent carcinogen was first painted on in twenty applications of 0.05 mg in 0.25% (w/v) benzene solution[5] in the course of 50 days (1.0 mg/mouse in total). Six days after the end of this treatment, one drop (about 0.05 ml.) of the hypochlorite solution was painted on and repeated forty-five times during 245 days (group 1). Other mice (group 2) were treated only with 4-nitroquinoline 1-oxide. The control mice were treated only with the hypochlorite (sixty times in 300 days). All of the mice treated were observed for 450 days from the start of the experiment.

The number in the parentheses shows the number of papillomas that regressed.

Hormonal Pregnancy Tests and Neural Tube Malformations

IN 1967 Gal, Kirman and Stern[1] reported a possible relationship between pregnancy tests using pills containing synthetic oestrogenic and progesterogenic hormones and the birth of a child with spina bifida. Of the 100 mothers of children with spina bifida, nineteen gave a history of pregnancy diagnosis by this means; only four of the 100 matched control mothers gave such a history.

A similar retrospective enquiry has been made between 1968 and 1970 in three centres, but including births of the clearly related malformation anencephaly as well as spina bifida. In the London series the control mothers were those having the next baby born in the same hospital. In the Exeter series the control mothers were matched for area of birth,

Table 1 Anencephaly and Spina Bifida in Babies Born to Mothers who had had Hormonal Pregnancy Tests

		Survey cases		Controls	
		Total	Pregnancy tests	Total	Pregnancy tests
South Wales	Spina bifida	29	2	112	7
	Anencephaly	31	2		
Exeter	Spina bifida	45	3	64	7
	Anencephaly	19	3		
London	Spina bifida	75	4	75	2
	Anencephaly	72	8	72	6
	Total	271	22 (20.1)	323	22 (23.9)

The number expected in survey and control groups if no difference exists is shown in parentheses. The difference between actual and expected numbers is within the standard error.

parity and month of conception. In the South Wales series the control mothers were those who had one baby with spina bifida or anencephaly and had a subsequent normal birth during the survey period and these were thus not controlled individually. The findings are summarized in Table 1. In these three surveys there is no significant association of pregnancy tests with pills containing oestrogenic and progesterogenic hormones and the birth of children with neural tube malformations.

Effect of *Avena sativa* on Cigarette Smoking

IN 1967, in India, I came across a practitioner of ancient Ayurvedic medicine who successfully used a decoction of common oats (*Avena sativa*) to cure the opium habit. While using an alcoholic extract of the plant on a group of opium addicts, several patients reported a loss of interest in smoking. The drug is listed in the United States Dispensatory and National Formulary[1–2], yet no reference has been traced regarding its application on smokers (Library of the Pharmaceutical Society of Great Britain, personal communication). I have therefore studied the effect of this drug on a group of smokers.

The active drug was an extract of healthy, fresh plant *Avena sativa* selected just before harvest. I used 1.5 parts of the crushed whole plant by weight in 5 parts by volume of 90% ethyl-alcohol, kept at room temperature with frequent agitation for 72 h and then filtered. The active constituent has not been identified.

Twenty-six cigarette smokers including healthy volunteers and chronic patients in the chest wards of Ruchill Hospital, Glasgow, including tuberculous patients, participated in the trial. The total duration of their smoking and the average number of cigarettes smoked per day in the preceding six months were recorded.

They were told that a drug was being tested which might affect their smoking, and that they were not to make any conscious effort to alter their smoking during the trial.

Table 1 Numbers of Cigarettes Smoked during Trial

	Group I (drug)		Group II (placebo)	
	Cigarettes per day before trial	Cigarettes per day after trial	Cigarettes per day before trial	Cigarettes per day after trial
	20	20	22	19
	25	10	30	28
	10	0	18	18
	12	0	14	14
	11	0	18	17
	9	0	17	18
	35	3	17	18
	25	7	8	18
	22	0	18	18
	20	7	20	18
	25	7	15	14
	20	10	10	9
	20	10	8	8
Av.	19.5	5.7	16.5	16.7

Each patient kept a daily record of cigarettes smoked, commenting on any changes in the craving for cigarettes. By random allocation, thirteen patients received the drug and the others received placebo for 28 days. The alcoholic extract (1 ml.) was diluted to 5 ml. and each oral dose was 5 ml. of this dilution given four times a day. No psychotherapy was used. No patients were taking any other drugs which could affect smoking. The patients in both groups were comparable in age, sex and smoking history.

The results of the trial are given in Table 1. In the drug group the total daily consumption by thirteen patients was 254 cigarettes; at the end of the trial it was seventy-four. Five had stopped smoking, seven had reduced it to less than 50% and in one no change had occurred. In the placebo group the total daily consumption at the start was 215, at the end it was 217. Smoking had been stopped by none, reduced to above 50% by six and increased by three; four reported no change.

The two groups were comparable in their smoking habits, since group I "before" (mean 19.5 ± 2.0 s.e.) is not statistically separable from group II "before" (mean 16.5 ± 1.7 s.e.); $t = 1.33$, $0.30 > P > 0.20$. Group I "before" is significantly different from group I "after" (mean 5.7 ± 2.0 s.e.); $t = 5.21$, $P < 0.001$. Group II "before" is not different from group II "after" (mean 16.9 ± 1.4 s.e.); $t = 0.180$, $0.90 > P > 0.80$. The mean differences between the groups due to treatment (group I "before"–group I "after") and (group II "before"–group II "after") are naturally equally significant; $t = 5.73$, $P < 0.001$. All these calculations are based on Student's t test.

In the drug group various degrees of loss of craving for cigarettes were reported. The drug seems to reduce the number of cigarettes smoked per day, along with diminished craving for smoking. Moreover, the reduction in smoking seems to continue even 2 months after the termination of the drug. The drug has never been used in dealing with the problem of smoking and, as this was the first instance of its use in smokers, its role and significance are worthy of further investigation.

I thank Dr G. J. Addis for help with statistical analysis and Professor V. D. Sharma for extracting the drug.

Possible Relationship between Smoking and Peptic Ulcer

EPIDEMIOLOGICAL studies have shown that the incidence of peptic ulcer is higher among smokers than non-smokers[1]. No reason for this association has been found. Since personality factors seem to play an important role in this disease, it could be argued that both the development of an ulcer and the habit of smoking heavily result from the same psychological traits and are therefore not related. Recently, however, Jacobson *et al.* demonstrated that nicotine markedly reduced secretion of water and bicarbonate from the pancreas by inhibiting the stimulating effect of secretin[2,3]. Since gastric acid is normally neutralized in the duodenum by pancreatic juice and, to a lesser extent, by bile, it was thought that nicotine might predispose to ulcer formation by preventing such neutralization. We have tested this possibility in rats treated with a combination of two gastric secretogogues (substances which stimulate secretion of gastric juice), pentagastrin and carbachol, which had been found to produce duodenal ulcers[4]. We have reported that when these secretogogues were administered in small doses known to produce an ulcer incidence of only 36%, the addition of nicotine raised the incidence to 90%, and the ulcers were multiple and very severe[5]. Nicotine, given alone, was without effect. This result indicated that nicotine sensitized the duodenum to the ulcerogenic effects of the two secretogogues used.

Subsequent studies demonstrated that the duodeno-ulcerogenic property of pentagastrin plus carbachol was due to the marked increased secretion of gastric juice elicited by these secretogogues[6]. We therefore investigated whether the pro-ulcer effect of nicotine was due to increased sensitivity of the duodenum to acid itself. We thought that since nicotine inhibits secretion of alkaline pancreatic juice, acid, perfused through the stomach, would not be neutralized and therefore should lead to the formation of duodenal ulcer.

A solution of hydrochloric acid was perfused through the oesophagus of rats, in amounts previously found to produce duodenal ulcers in about one-third of the animals[1]. Female Upjohn rats (derived from Sprague–Dawley strain), of an average weight of 220 g, were fasted overnight. On the following morning, a tygon tubing (22 gauge) was inserted, under ether anaesthesia, into the cervical oesophagus through a small skin incision. The tip of the tubing lay 0.5–1.0 cm above the cardiac opening of the oesophagus. On recovery from anaesthesia, the tubing was connected to a syringe mounted on a constant infusion machine, containing either HCl 0.12 N (groups I and II) or water (group III). Acid and water were perfused at a rate of 3.0 ml./h for the first 10 h, then at a rate of 1.5 ml./h for the next 14 h. The fluid flowed from the oesophagus to the stomach, then entered the duodenum through the pylorus. Group I (sixteen rats) was also infused subcutaneously with saline at the rate of 0.54 ml./h, whereas group II (fourteen rats) was infused subcutaneously with a solution

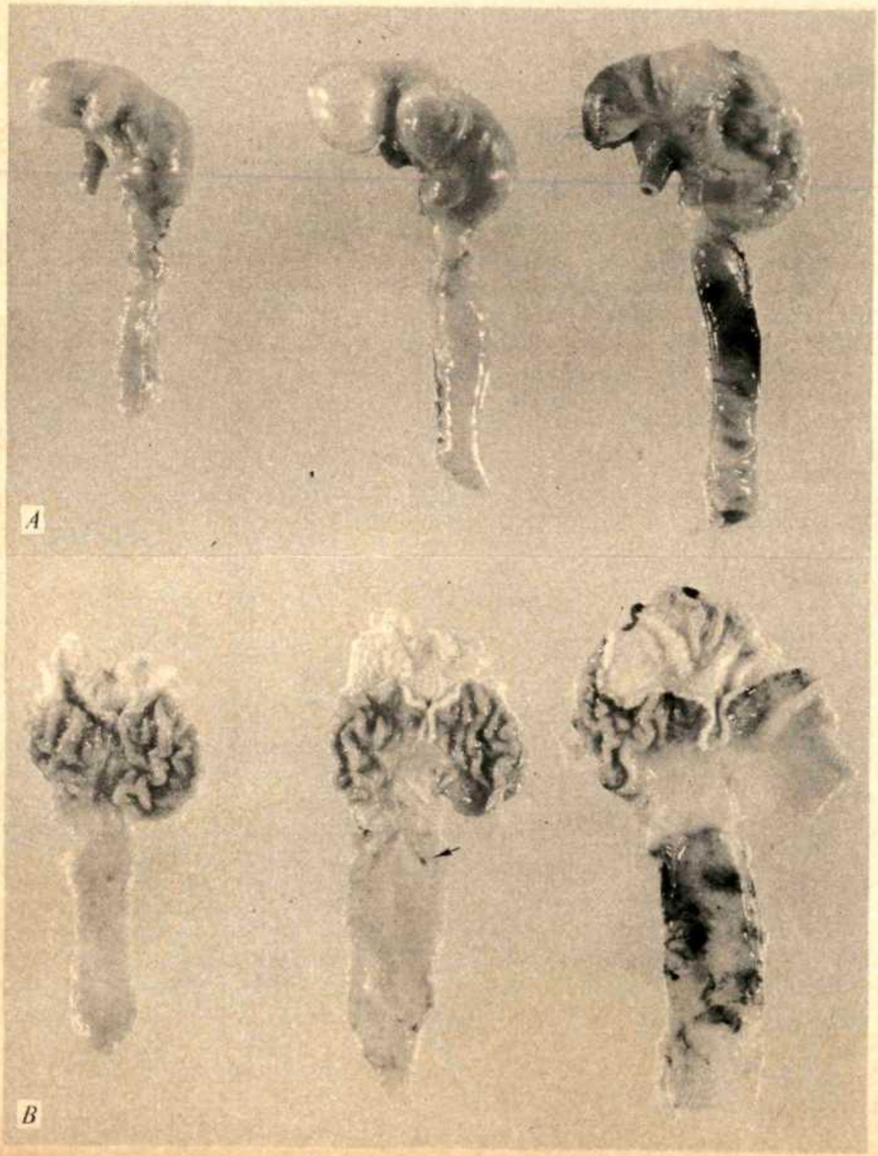

Fig. 1 Duodenal ulcers produced by acid (perfused in oesophagus) and nicotine (infused subcutaneously). *A*, External view of stomach and duodenum *B*, Same stomachs and duodenums after opening along mesenteric attachment (duodenum) and greater curvature (stomach). Left, water perfused in oesophagus, nicotine SO_4 infused subcutaneously (group III). No ulcer. Centre, acid (HCl 0.12 N) perfused in oesophagus, saline infused subcutaneously (group I). Small duodenal erosion (arrow). Right, acid (HCl 0.12 N) perfused in oesophagus, nicotine SO_4 infused subcutaneously (group II). Extensive, deep and multiple duodenal ulcers. Note that the gastric mucosa is intact.

of 20 µg/kg/min of nicotine sulphate in saline also at the rate of 0.54 ml./h. Group III (twelve rats) received the same amount of nicotine sulphate subcutaneously as group II, but water instead of acid was perfused through the oesophagus. During treatment, the animals were conscious at all times and placed in a cylindrical cage that prevented them from bending and thus from chewing the tubing. Food and water were withheld throughout the experiment. All rats were killed after 24 h of treatment. The stomach and duodenum were dissected out as a single unit and opened along the mesenteric attachment for the duodenum and the greater curvature for the stomach. They were then examined with a ×2 binocular magnifier for the presence of ulcerations.

Table 1 shows that when acid alone was perfused (group I), duodenal ulcers were found in 31% of animals. When nicotine sulphate was also given (group II), the incidence reached 93%. The ulcers in the animals treated with acid and nicotine were also more numerous and more severe than those in animals receiving acid only. Finally, nicotine alone (group III) produced no ulcer. Fig. 1 shows duodenal ulcers produced by acid in the oesophagus plus nicotine, administered subcutaneously.

Table 1 Sensitization by Nicotine to Duodenal Ulcers produced by Acid Perfusion

Group	I Acid perfused * + saline s.c.	II Acid perfused + nicotine SO_4 † s.c.	III Water perfused + nicotine SO_4 s.c.
No. of animals	16	14	12
Duodenal ulcers			
Incidence %	31	93	0
Severity 0–3+	0.3	1.5	
Ulcers/duodenum	0.4	1.6	
Ulcer index ‡	3.8	12.4	0

Animals were killed after 24 h

* Acid: HCl 0.12 N perfused through the oesophagus

† Nicotine SO_4: 20 µg/kg/min infused subcutaneously.

‡ Ulcer index: sum of (*a*) % incidence (divided by 10), (*b*) severity in pulses and (*c*) numbers of ulcers per duodenum.

These results strengthen the hypothesis that nicotine sensitizes the duodenum to the ulcerogenic property of acid flowing from the stomach. Although, in the present study, the acid was from an exogenous source, the acid concentration and the perfusion rate were close to the amount of secretion formed by the rat stomach when maximally stimulated with histamine[8]. Thus, acid alone can initiate a duodenal ulcer provided either the concentration and rate of flow are high enough (as shown by previous studies[7]), or the formation of alkaline juice from the pancreas is reduced by an agent like nicotine.

The amount of nicotine in one cigarette is about 15–30 mg. Approximately 50% of cigarette smoke can be expected to be inhaled by a heavy smoker and it has been estimated that 90% of nicotine in inhaled smoke is absorbed into the circulation[9]. If man reacts to nicotine as the rat does, it seems likely that nicotine absorbed chronically through smoking may contribute to ulcer formation and to ulcer recurrences by reducing secretion of alkaline pancreatic juice via inhibition of secretin.

Orientation-specific Masking of Letter Features

THE ability to detect or resolve a target consisting of a briefly presented bar or grating is diminished by preceding or following it with a grating of similar orientation. This orientation-specific masking is maximal when target and mask have the same orientation and the impairing effect of the mask decreases monotonically with increases in the angular difference between target and mask, reaching half its peak value at a difference of about ±15° (refs. 1–4). These findings have generally been attributed to the properties of single cortical cells which seem to act as orientation analysers and which have been shown to possess similar angular bandwidth tuning[5-7]. Such selective masking may be used to compile pattern feature lists and to elucidate their organization in the recognition of complex patterns[8]. But we know of no studies of selective masking of multi-attribute patterns. Accordingly, we have explored the feasibility of selectively masking orientational features of letters to produce predictable confusions in a typical pattern recognition task.

The recognition stimuli were eight upper case English letters: —A, Z, —Y, N, —H, T, —O, X. A backward masking paradigm was used whereby the letters were presented singly in field 1 of a Gerbrandt three-channel tachistoscope followed after a delay by a masking grating in field 2. The letters were Letraset Futura Bold (96 point) transferred to white cards. At the viewing distance of 580 mm they subtended an angular height of 2° 31′. The component bar width of the letters subtended 40′. They appeared as high contrast black letters on a white background with a luminance of 48 mLamberts and were exposed for 2 ms.

The mask formed a 10° 55′ square surrounding the location where the letter had appeared. This square was filled with a black and white square-wave grating with an angular stripe width of 12′. Mask duration was fixed at 55 ms. In the two experimental conditions the orientation of this grating was either horizontal or vertical.

A delay of mask from stimulus offset was chosen for each subject which yielded approximately 60% recognition of the letters with the vertical mask, after some practice. These delay values ranged from 12–37 ms between subjects.

Eight subjects made forced choice recognition responses to the block randomized letters with each letter occurring six times in each condition. A preliminary analysis of the data in Table 2 reveals that the letters which were least well recognized were those with components of the same orientation as the masking grating. Consider the letters Z and N which have the same form subject to a 90° rotation. With a vertical mask Z is better recognized than N, whereas N is markedly better recognized than Z with a horizontal mask. The only anomalous letter is A which is not masked by the horizontal grating. This letter, however, is unique among those studied in that even if its horizontal component is removed the residual inverted V is sufficient for correct recognition. Furthermore, this oblique feature may fall within the masking angular bandwidth of a vertical grating, as we discuss later.

The crucial test of orientation specific masking is in the nature of the confusional errors. Considering first the interaction of horizontal letter components with the horizontal mask the overwhelming proportion of errors to T is Y, the only other letter with a single vertical feature. Similarly, H is most often confused with N, the best solution for the residual two verticals, and Z with X.

When H and T are masked by the vertical grating, however, both are most often confused with Z, a solution compatible with a residual horizontal component. Y with its vertical stem masked is most often confused with X, and N with X and Y. It seems, therefore, that the pattern of confusions changes according to the orientation of the mask, and these changes are consistent with the assumption that orientation-specific masking of letter components takes place with the response determined by the best fit to the residual unmasked components.

Table 1 Percentage of Errors in Letter Recognition as a Function of Mask Orientation

Subject	Vertical mask	Horizontal mask
	Error %	
MI	14.6	2.1
ST	37.5	10.4
PH	27.0	10.4
LE	47.9	18.8
JI	60.4	22.9
MA	41.7	29.2
JA	22.9	6.3
GA	41.7	4.2
$\bar{X}$	36.7	13.0

Errors are totalled over letters.

The vertical grating was a more effective mask for every subject (Table 1). For all but one subject the overall increase in errors due to the vertical mask exceeds 250%. Furthermore, for each target letter the error total across subjects is greater in the vertical mask condition, except for the letter O which was always correctly recognized (Table 2). Because orientation-specific masking holds over a range of angular similarities, and the oblique components of the letters fall nearer to the vertical, they might be more vulnerable to the vertical mask. But with the exception of letter A which has obliques 22° off vertical and which was peculiarly vulnerable to the vertical mask, the oblique components were 32°–38° from the vertical. At this separation masking can be expected to be negligible[1-4]. Furthermore, errors to the letter T increase 50% with the vertical mask although this letter contains only one vertical and one horizontal component. The greater efficacy of the vertical mask is therefore not explicable solely in terms of the particular orientation characteristics of the letters used. Letters are usually encountered in horizontal arrays, however, and it may be that there are orientational aspects of letter processing other than the orientation of components.

Table 2 Confusion Matrix of Errors to Letters Masked by Vertical and Horizontal Gratings

Mask orientation	Target letter	Error type and frequency	Error total	Error %
Vertical	A	11X · 3Z · 3H · 1N	18	37.5
	Z	3T · 2A · 2X · 2Y · 2O · 2N	13	27.0
	Y	5X · 3A · 2T · 2N · 2Z	14	29.2
	N	7X · 7Y · 4A · 3T · 2Z	23	47.9
	H	9Z · 7Y · 7N · 5T · 3A · 2X	33	68.8
	T	8Z · 6A · 6Y · 4N · 2H · 1X	27	56.3
	O		0	0
	X	5Z · 3Y · 2H · 2T · 1A	13	27.0
Horizontal	A		0	0
	Z	5X · 2Y · 2A · 1N · 1H	11	22.9
	Y	2X · 1Z · 1H	4	8.3
	N	2H · 1X · 1A	4	8.3
	H	10N · 1O	11	22.9
	T	16Y · 1H · 1O	18	37.5
	O		0	0
	X	3A	3	6.3

Erroneous responses are listed in descending order of frequencies for each target letter. Data are totals across eight subjects.

We used a grating frequency of 2.5 c/degree, but further manipulation revealed that masking decreased steeply with increases in spatial frequency over an investigated range of 1.25 to 20 c/degree. Two explanations for this suggest themselves. Apparent contrast varies inversely with spatial frequency[9] and it seems plausible that apparent contrast determines the efficacy of a masking grating. Second, as grating frequency decreased it approached the value of the bar width of the letters. Thus spatial frequency specific masking[10] could be expected to increase, providing another source of selective masking.

A further implication of these results is that the masks used to terminate the visual persistence of letter arrays may require critical attention. Such "noise" masks seldom have the distribution of spatial frequencies and orientations which is desirable for feature masking. The controversy between integration–degradation and interruption–erasure theories of masking may well depend on the choice of mask. The common choice of a mask in terms of its efficacy when superimposed on the target may maximize integrative masking but will be irrelevant to feature masking if the results of Campbell and Kulikowski[3] can be generalized.

Organochlorine Pesticide Residues in Harbour Porpoises from the Bay of Fundy Region

ORGANOCHLORINE pesticide residues, together with polychlorinated biphenyl compounds of industrial origin, occur in many forms of life in the marine ecosystem. These compounds are concentrated through progressive trophic levels until relatively high levels accumulate in lipid-rich tissues of predatory seals, toothed whales and sea birds[1-3].

The highest levels in marine mammal tissues published so far were in the blubber of ringed seals, *Pusa hispida*, from the

Table 1 Organochlorine Residue Levels from Blubber and Liver of Porpoises (*Phocoena phocoena*) from New Brunswick and Nova Scotia (1969, 1970)

			Average residue levels in p.p.m. in extractable fat					
Sex status	Sample size	Tissue	Dieldrin	*p,p′*-DDE	*p,p′*-DDD	*o,p′*-DDT	*p,p′*-DDT	ΣDDT
Weaned and adult males	12	Blubber	9.24 (4.4 –13.1)	121.57 (45.7 –181.0)	48.16 (27.4 –100.0)	17.84 (9.6 –26.7)	119.18 (60.6 –175.0)	306.74 (150.8 –520.0)
	3	Liver	0.09 (0.01–0.15)	1.37 (0.92–1.61)	0.98 (0.86–1.20)	0.03 (0.01–0.04)	0.35 (0.18–0.47)	2.69 (1.97–3.32)

	8	Liver	0.06 (0.02–0.13)	0.50 (0.25–1.28)	0.46 (0.20–0.93)	0.02 (0.01–0.08)	0.37 (0.10–1.28)	1.36 (0.61–3.57)
Pregnant and/or lactating females	6	Blubber	1.37 (0.1 –2.4)	25.50 (15.0 –40.0)	13.47 (7.3 –24.0)	2.41 (0.1 –8.0)	27.75 (14.1 –50.0)	69.03 (40.0 –122.0)
	2	Liver	0.02	0.26 (0.25–0.27)	0.14 (0.12–0.16)	0.01	0.07 (0.06–0.08)	0.48 (0.46–0.50)

Gulf of Bothnia (ΣDDT range 11–130 p.p.m., mean 120 p.p.m.), and in the blubber of grey seals from the Baltic Sea (ΣDDT range 97–310 p.p.m., mean 170 p.p.m.)[2]. One porpoise, *Phocoena phocoena*, from the east coast of Scotland contained a total residue concentration (dieldrin + DDT compounds) of 73.3 p.p.m.[4].

Sixty harbour porpoises, *Phocoena phocoena*, were collected by D. E. G. in western North Atlantic waters in 1969–70. Blubber samples from thirty and liver samples from twelve animals were chilled to sea water temperature (about 10° C) and frozen to −20° C as soon as field conditions permitted (2–7 h). A two column fractionation separated organochlorine insecticides from the polychlorinated biphenyls (PCBs). The first step consisted of a 'Florisil' column for the separation of fatty coextractives from organochlorine insecticides[5]. Up to 10 μg PCBs or 1 μg of DDT, DDE, or DDD were handled by the column to give a 90 to 100% separation. For best separation, two elutions with quantities most favourable to each group of compounds were made. Eluates were concentrated almost to dryness and redissolved in hexane for gas chromatography. Qualitative residue confirmation was achieved principally with thin-layer chromatography. Percentage recoveries were checked periodically by fortification directly into the oil obtained from hexane extraction. Average recoveries were: *p,p′*-DDE, 98%; *o,p′*-DDT, 91%; *p,p′*-DDT, 90%; *p,p′*-DDD, 95%; dieldrin, 89%. Data in Table 1 are not corrected for percentage recovery. Further study of the PCB residues is in progress. Their occurrence was, however, quite high, ranging from one to three times the levels recorded for *p,p′*-DDE.

Average dieldrin, ΣDDT levels in pregnant and lactating females were much less (1.37 p.p.m. of dieldrin, 69.03 p.p.m. ΣDDT) than in immature and resting females' blubber (7.75 p.p.m. dieldrin, 214.27 p.p.m. ΣDDT). Three sucklings had high levels (range 75.1–186.7; mean 138.8 p.p.m. ΣDDT). Residues may move into the depot fat in the foetus, or to the neonate through milk, or both.

The average ΣDDT level in the blubber of males (306.74 p.p.m., excluding sucklings) seems to be the highest published for a wild population of any mammal. The small sample size precludes speculation on residue variation at this time with respect to age, season and distribution.

These results are ominous enough to merit further immediate attention to the status of contaminants in the higher trophic levels of the Bay of Fundy food web.

Field studies were supported by a grant from the National Research Council of Canada. Other assistance was given by the Canadian Tuna Company of St Andrews and Marine Research Associates of Lord's Cove, Deer Island, New Brunswick.

Earliest Indian Human Remains found in a Late Stone Age Site

THE discovery of human remains from a Late Stone Age site in the village of Sarai Nahar Rai in Uttar Pradesh has provided the earliest available skeletal evidence of man in the Indian subcontinent. This northern Indian site, which is in the district of Pratapgarh, lies about 38 km north of Allahabad city and 33 km south-west of Pratapgarh town, connected by road. It covers about 2,700 m^2 (about lat. 25° 48′ north and long. 81° 50′ east) and is about 9 km west of Bishnathganj Railway Station on the Allahabad–Fyzabad line of the Northern Rail-

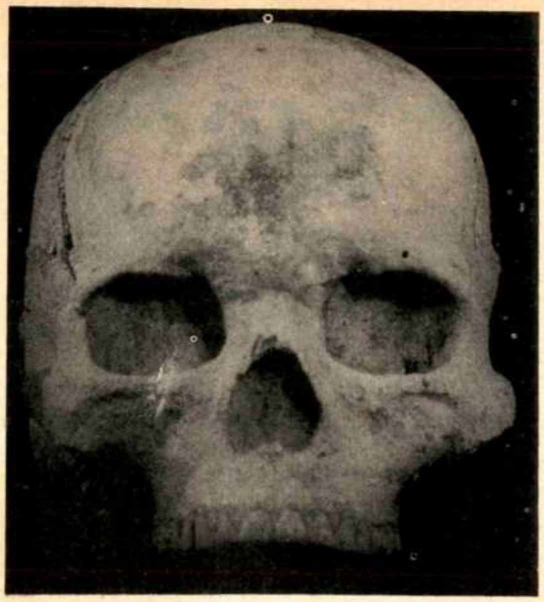

Fig. 1 Norma frontalis of skull of skeleton No. SRN-4 (photograph by courtesy of the Anthropological Survey of India).

way. It was discovered in 1968. The eastern sector of the site—about 600 m^2—had been badly eroded and there was visible evidence of a cluster of human graves, the only such example to have been reported from the plain of the Ganga.

A considerable number of microliths and waste flakes made principally of quartz were collected from the surface of the site, where there was a regular microlithic industry. The finished tools, which mostly had steep retouches, included blades, points, piercers, burins, lunates, triangles, trapezes, arrowheads and borers. Heavy tools were conspicuously absent. Chips of charred animal bones were found scattered all over the surface. Some irregular and circular markings on the eroded surface of the site were noticed. These finds represent the debris of a spot where a small group of people had camped.

In March 1970 I conducted an excavation on behalf of the Anthropological Survey of India at the request of the Archaeological Department of Uttar Pradesh, assisted by Mr Anadi Pal. Digging yielded an articulated, almost complete and undamaged skeleton (No. SRN-4) buried in a grave; only the mandible and right humerus were missing. Another eight, badly damaged skeletons were lying nearby, exposed because of heavy erosion of the top soil. The right clavicle and some fragmentary bones of one of these skeletons (No. SRN-5) were removed for examination, and other fragments were sent for radiocarbon analysis to the Tata Institute of Fundamental Researches, Bombay. Some skeletons show evidence of the early stages of petrification.

All skeletons were buried within the deposit of layer 1, and No. SRN-4 was 14 cm below the present surface. This layer is composed of compact and hard silt of a darkish colour. When I revisited the site in May 1971, accompanied by Dr D. K. Sen, director of the Anthropological Survey of India, and Mr P. Gupta, I could locate the skeletal-bearing layer 1 against an exposed section of a nearby small tributary of the Sai River flowing across the district a few kilometres to the north of the site. The layer is about 32 cm thick, resting on an under layer of about 26 cm made up of silt mixed with kankar. Immediately below it is a layer of sandy silt of about 17 cm thick. The nature of the deposit indicates minor climatic oscillations, but generally a dry phase in the post-Pleistocene period.

Clay pots prepared by coiling and baking were found embedded, possibly in some pattern, in most of the graves. The upper part of most of the pots was, however, eroded away, leaving a circular cross-section of pots projecting from the surface.

There is evidence that the dead were regularly disposed of in a supine posture, usually in a normal extended position with the head to the west (some, however, between west and south but usually within a few degrees of west).

Skeleton No. SRN-4 belonged to a male who was older than 30 when he died. The skull (Fig. 1) is virtually complete and well preserved, and lacks only the mandible. The head is sub-rounded with the keel of the vault somewhat flattened. Seen from the top, the contour is "birsoides". In profile, the forehead is steep, and the superciliary ridges are mesially developed. The face is broad and short with moderately compressed orbits, while the nose is flattish-broad with a marked depression at the base. The mastoids are strong. The cranium has a complete upper dentition which is highly attrited. The wear of the upper incisors clearly indicates that the owner of the skull had the habit of biting in an "edge to edge" manner. The cranial index is 76.04 (mesocranic), nasal index 53.61 (chamaerrhine) and orbital index (left) 74.70 (chamaekonchic).

The radiocarbon analysis of a bone sample (index No. TF-1104; depth 5 cm; layer 1) has provided an absolute date of 10,050 ± 110 (10,345 ± 110) BP (the first date is based on half life of radiocarbon of 5,568 ± 30, and the date parentheses are based on the value of 5,730 ± 40 for the half life of radiocarbon)[1].

These remains clearly predate by about 5,800 yr the previous earliest record of man, from the Late Stone Age site at Lekhania in Uttar Pradesh and dated by radiocarbon.

A detailed report on these finds will be published later.

More about Dowsing

THE article on "Dowsing Experiments" by Foulkes[1] describes some work with which I was concerned and reflects the considerable effort involved in the planning and subsequent analysis of the trial. It does not, however, bring out some of the things which went wrong, which both modify and add to Foulkes's account and which illustrate problems which future experimenters would presumably wish to avoid. My part in this work was the carrying out of the statistical analysis and data presentation which Foulkes reports and it is with these aspects that I am concerned. My remarks are made after reference back to notes I made during the analysis period.

First, the pattern of objects illustrated in Fig. 1 was, indeed, that plan which was originally produced and the objects were nominally laid out in that manner. During some trials with a conventional mine detector, however, subsequent to the dowsing experiment, it was found that row E had not been laid out exactly as planned. Specifically, the objects planned for E6 to E15 were misplaced and actually buried in E5 to E14 and the remaining "blank", planned for E5, was in fact "buried" in E15. The analysis, which was by this time complete, had to be redone and the Tables given in the later parts of the paper are correct. How this error was not discovered by at least one of the gangs of men who were responsible for burying another class of object is still a mystery.

The results of the two dowsers, experimenters six and seven, were not in Figs. 5 and 6 of Foulkes's article. The results of these experimenters were very interesting. They wandered off unsupervised (that is, without an accompanying "caddy" to record their responses). Their results were very similar for both types of ground. The results of experimenter six on the natural ground are given in Table 1.

Table 1 Dowsing Results of Experimenter Six on Natural Ground

	Object buried					
	B	M	C	W	P	Totals
Response						
M	1	10	2	3	6	22
P	2	11	5	6	7	31
O	1	19	0	1	27	48
(Blank)	36	0	33	30	0	99
Totals	40	40	40	40	40	200

B, Blank; M, metal mine; C, concrete block; W, wooden block; P, plastic mine.

Table 1 has a similar form to Table 2 in the article. On the original score card the dowser was instructed to record M for metallic mine, P for plastic mine and O for nothing present. When questioned about the response O and the blanks left on the score sheet, experimenter seven said that O had been used to mean that an object was present but its identity was unknown and that a blank had been left when a square had been dowsed and nothing found. Table 1 shows clearly a remarkable degree of association between the blank response and the presence of B, C or W and between the O response and the presence of M or P. Since the statement about the meaning of O was made "*a posteriori*" it does not necessarily indicate an ability to dowse and as the two dowsers traversed the course together their results are not necessarily independent.

The experiment was therefore repeated by experimenter seven and his results are, in fact, those attributed in the article to experimenter eleven. There was no significant association on this second attempt without experimenter six, who was not retested. This dowser was the soldier illustrated in Fig. 3 of the article, a Nigerian, who unfortunately could not be retested. These results, although inconclusive because of the lack of experimental control, do suggest that something peculiar occurred on this occasion which might be worth further investigation. Two different conclusions, all too common in this type of work, can be drawn. Either some form of ability was demonstrated (although peculiarly recorded and interpreted) or a breach of security of the trial (including the possibility of cheating) took place. It can be argued that it would be possible for an unsupervised student to have prodded the ground (for example with one of the dowsing rods) and at least detected an object present, since for control purposes small wooden pegs indicated the position in which an object, if present, would have been buried. Although this form of cheating may well have taken place on this occasion it does not explain how mines and other objects might have been differentiated. Indeed, since the basic concern was with methods of detecting underground mines, a proven ability to detect the difference between a mine and an object (for example a stone), even by prodding, could have been of considerable importance.

There is also slight evidence that a positive response was more closely associated with the presence of a wooden block than with a concrete block—especially on the raked ground. Although this may be a spurious result, the wooden block may have absorbed more moisture than the concrete block, thus altering the drainage pattern and hence the surface appearance of the ground.

Dowsing Experiments Criticized

My photograph appeared in Foulkes's article, Dowsing Experiments[1], without prior reference to me, and I would like to make the following comments on the article.

The experiments carried out at the Military Engineering Experimental Establishment (MEXE) did not involve true "dowsing" as they were not water divining. Although experienced dowsers can locate buried objects such as cables, pipes and the like, these experiments were a search for objects unfamiliar to those taking part. Those I spoke to made no claim to achieve success, but agreed to the trial as an interesting experiment that might be of practical use. It was also evident to all that, to be of practical use, map dowsing must be used when walking over a live mine field. I agree that this experiment was a failure although one man was successful far beyond the bounds of chance.

The "flow in a pipe" experiment is not one which I would attempt, although I could probably locate the pipe either full or empty. No mention is made of the dowser's experience in this particular kind of search. I consider this test valueless, if he had no such experience.

I would like to emphasize that I was not instructing anyone in dowsing during the exercise at Chatham. The object was to find a number of men who could usefully develop into proficient water diviners. I do not think it possible to instruct anyone. Of those involved, 10%, not 25%, found accurately my second flow line; their judgment coinciding with mine and confirming my classification of them as sensitives.

I still maintain that the well referred to was correctly sited on one of the flows in the upper chalk. I predicted that the water would be near the bottom of the upper chalk and detectable by drilling through the clay to the chalk. This has not been done, as the drilling rig was removed before it had passed through the clay stratum. This was, therefore, not a dowsing failure.

The test over the 42 inch pipe seems to have been made by some of the 10% of "sensitives", who had no real dowsing experience. Even over natural fissure flows I would not have expected these novices to assess quantity.

Foulkes's description of the V rod movement was inaccurate. If the rod is held firmly in the normal way, another person can press the tip up or down, and, when released, the rod will return to its original position without any additional effort by the holder.

The Rocard experiment proves nothing. There are many dowsers who cannot dowse in rubber soled shoes. If Rocard, thinking he had used magnetized iron in his elbow joints, actually used non-magnetic iron, the experiment could have had the same result. It is a pity that Foulkes does not seem to have consulted any other authority than Rocard.

BOOK REVIEWS

Social Biology

Social Implications of Biological Education. Edited by Arnold B. Grobman. Pp. 134. (Darwin: Princeton, New Jersey, April 1971.) $5.95.

THIS book was planned by a Committee of the American National Association of Biology Teachers for those who would welcome thoughtful reviews of pressing social problems associated with advances in the biological sciences. It is the report of a national conference of NABT held in 1969, in which papers prepared by distinguished biologists, who have exhibited a concern for significant social problems, are followed by the prepared statements of three panelists, which support, contradict, extend or restrict the major papers. The three members of each panel include at least one additional specialist in the field of the major speaker and one practising school teacher. The statements of the panels are followed by accounts of the question and answer sessions.

Four major topics, medicine, behaviour, genetics and population, are dealt with in this manner, and, owing to Dr Grobman's skilful editing, this technique has produced a lively and readable volume. Such questions as "Should the government support and control scientific research?", "Should euthanasia be practised?", "Is free-will an obstacle to technological progress?", "Are differences of intelligence a matter of race?", "Is birth control a solution to the population problem?" and "Should man control his genetic resources?" are ably discussed from differing viewpoints.

The section on medicine is introduced by a paper on "The Social Implications of Medicine" by Michael and Lois Debakey of the Baylor College of Medicine, Houston, Texas, who discuss the growing discrepancy between the achievements of research and technology and their application to human life. The importance of the science teacher's role in conveying not only basic concepts, the philosophy and methods of science, but also the social implications of medical science, so that each student may recognize his responsibility in helping to shape public policy in this field, is clearly brought out.

James V. McConnell of the University of Michigan introduces the topic of behaviour in a controversial paper on "Ethics and Behaviour", in which he discusses life from a behaviourist's standpoint, and a paper by Bruce Wallace of Cornell University entitled "Genetics and Genetic Manipulation" opens the section on genetics. This latter gives an interesting treatment of biological races, and comments on recent work on "racial intelligence", as well as considering eugenics and genetic engineering. This is followed by a stimulating paper entitled "Can Teachers Tell the Truth about Population?" by Garrett Hardin of the University of California.

The last chapter departs from the pattern adopted for the rest of the book. It is based on the banquet address by Claude Welch on "Evolution—the Reluctant Revolution", in which the nature of conceptual revolutions is discussed.

This volume is not intended to be a complete compendium of the social implications of biological education. It is selective and omits some very important problems. For instance, there is no section devoted to ecology, and the whole vital area of the control of pollution and the redressing of the environmental balance is only hinted at. The reason for this omission might well have been that one of the few social problems, which American biology teachers of a generation ago thought appropriate for their consideration, was conservation. In this area, NABT played an active part and, under the leadership of the late Dr Richard Weaver, the Association produced a *Conservation Handbook,* which has been highly regarded.

Furthermore, the treatment of those topics, which are dealt with in this volume, does not set out to present all possible points of view. The aim is rather to present a number of thought-provoking and related statements on current problems for teachers to consider. Where the chosen topics have implications, which fall into the two broad areas of social–political and moral–ethical, it is in the former area rather than in the latter that problems are explored.

This should be a particularly useful book for teachers of the life sciences, who wish to discuss with their students those "problems generated at the interface between science and society". As science becomes broadly integrated into all phases of our culture, its significance as a part of a general education becomes more important and the aims of science teaching will need to go beyond the restrictive context of the special disciplines and consider science in relation to mankind. It is clear from the discussions reported in this volume that it will meet a need for science teachers who are now expected to take on an entirely different kind of responsibility from that for which they have received preparation. ELIZABETH PERROTT

Parasitic Insects

Parasitic Insects. By R. R. Askew. Pp. xvii+316. (Heinemann: London, June 1971.) £3.50.

THIS book is divided into two sections; the first deals with insects having parasitic adults and the second with protelean parasitic insects. The author adopts a very broad view of parasitism and a wide range of diverse associations are described under this umbrella definition. The first section is introduced by a description of the mouth parts of adult parasitic insects, which possibly would have been more easily comprehensible had it been treated from the point of view of adaptive radiation and with a little more emphasis on function and the physiology of digestion of imbibed host tissue. Some treatment on the ecology of the host body environment and the alterations (for example, the histopathological changes) inflicted on it by the parasite would have been useful and may even give a lead to explain the absence of anticoagulants in the saliva of some of these species. For a parasite does establish a physiological association with the tissues on the surface of, or inside, the body of its host, even though the association is primarily to provide food for the parasite. This omission is not altogether the fault of the author, for much remains to be done in this field.

Chapters 2–5 deal with lice, fleas, blood sucking flies and Diptera pupipara and chapter 6 with bugs, earwigs, beetles and moths as a "convenient" grouping of other insects parasitic as adults. I believe that the bugs should have been dealt with in a chapter on their own. The approach to these organisms is from the ecological standpoint and there is undoubtedly a wealth of information here, with substantial reference to up to date literature. The final chapter in this section deals with blood sucking insects as vectors of human disease, but more could have been done on this aspect of the subject —for example, some reference to the factors influencing the movement of trypanosomes in the insect gut and the passage either to the proboscis or to the hindgut preparatory to transmission. The insect body is, after all, an environment for these pathogens and they must show physiological adaptability to it. In spite of these apparent criticisms there is no doubt that the author has drawn together much information of considerable value for undergraduate students and as introductory reading for postgraduates specializing in ectoparasites. In the introduction (page X) the author states that the term parasitoid will not be used in the book, but he proceeds to do so on page 111! The author is obviously very much more at home when writing on parasitic Hymenoptera (chapter 8) and presents an excellent review of their structure, function and ecology extending over seventy-three pages (compared with ninety-four pages for all insects with parasitic adults). Thirteen families of protelean parasitic Diptera are likewise covered in some detail and these chapters are eminently suitable for postgraduate reading. The characteristics of biological control of insect pests form the substance of chapter 10. Fly larvae which parasitize vertebrates (chapter 14) might appropriately have been included in the first section.

This book fulfils a real need for a variety of students, it is well composed, is illustrated with clear line drawings of the highest quality, and the whole is completed by a substantial list of relevant references.

DON. R. ARTHUR

Life on Earth

The Nature of Life: Earth, Plants, Animals, Man and Their Effect on Each Other. By Lorus Milne and Margery Milne. Pp. 320. (Cassell: London, August 1971.) £5.50.

Lorus and Margery Milne have produced a beautifully illustrated book about the life on this planet. It is not a technical book, but the text is informative and full of interesting miscellaneous facts, for example, that the shell of the foraminiferan *Globorotalia* coils clockwise when the climate is warm and anticlockwise when it is colder and that this has enabled geologists to obtain a measure of the temperature of the sea at different times.

The book covers all the continents of the world as well as the oceans, describing the geology, climate and forms of life to be found there. It would have been greatly improved by the use of good maps of the places being described. As it is, the almost complete absence of any maps means that one is constantly coming up against the names of faraway places, the locations of which are only dimly remembered from school geography.

The final chapter is about the damage which the human species has done and is continuing to do to its environment. Although the message is now a commonplace one, it is difficult not to be impressed all over again by the fact that one species of mammal and one species of bird become extinct, on the average, every eight months, often as the direct result of human activity.

The Milneses should succeed in inducing in the reader the desire to visit and explore as they have done and to see for himself the beautiful and varied faunas they describe.

MARIAN DAWKINS

A Young Science

An Introduction to Psychopharmacology. By Richard H. Rech and Kenneth E. Moore. Pp. xii+353. (Raven: New York, 1971. Distributed in the Eastern Hemisphere by North Holland, Amsterdam.) £4.65.

Psychopharmacology and the Individual Patient. Edited by J. R. Wittenborn, Solomon Goldberg and Phillip R. A. May. Pp. 256. (Raven: New York, May 1971. Distributed in the Eastern Hemisphere by Pitman Medical and Scientific, London.) £5.50.

PSYCHOPHARMACOLOGY is somewhat isolated from disciplines such as neuropharmacology, psychophysiology and neurochemistry and is not yet integrated with its most relevant basic sciences, pharmacology and experimental psychology. Only psychiatry has developed a common area with psychopharmacology, that of drug therapy in mental illness. The reasons for this state of affairs which continues nearly twenty years after the discovery of the first of the modern psychotropic drugs, chlorpromazine, lie in the recent historical development of the subject. Most, if not all, of the important new psychotropic drugs were discovered by serendipitous accident. Thus, chlorpromazine and imipramine were first noted to have potentially useful actions in patients. Psychiatrists using these drugs on the wards and in their out-patient clinics quickly realized that real therapeutic advances were being made with essentially new drug types. Pharmacologists and psychologists then sought actions of these drugs both in animals and in normal humans which would provide some rationale for their therapeutic effects.

In spite of all the research effort of the past two decades, the mode of action of most psychotropic drugs remains obscure or, more strictly speaking, the clinical relevance of the pharmacological actions which have been found remains unproven. For example, for some time after the introduction of the tricyclic anti-depressants, their mode of action was unexplained. Eventually it was found that they inhibited the reuptake of noradrenaline from the synaptic cleft. The other class of anti-depressants, the monoamine oxidase inhibitors, had from the start been assumed to owe their clinical action to that implied in their generic name. However, it now seems possible that they, too, inhibit noradrenaline uptake and that their enzyme-inhibiting properties may be less relevant.

For these and many other reasons, psychopharmacology has remained a loose federation of disciplines rather than a coherent subject, and at the clinical level it is probably the most empirical branch of therapeutics. These two multi-author American books represent two different approaches to the problem of maturing psychopharmacology from the empirical to the rational. *An Introduction to Psychopharmacology* aims at providing for the neophyte background reading in cognate subjects. Two rather breathless chapters attempt the impossible task of outlining pharmacology, psychology, neuroanatomy, and neurophysiology in eighty pages: there are many basic texts more suitable for this purpose. The remaining chapters are much more successful, covering biochemical aspects, the limbic system, electrophysiology, conditioning and animal testing of new drugs, with two clinical chapters on tranquillizers and anti-depressants. Except for the chapter on anti-depressants which is in the "in my experience" style, the scientific standard is high and the material presented is critically appraised. Useful key references and reviews are included. The chapter by K. E. Moore on "Biochemical correlates of behavioral effects" is very balanced and avoids the overstated claims of those who believe that biochemical mechanisms in adult mental illnesses are already apparent.

Psychoparmacology and the Individual Patient is disappointing and will be of interest to very few people. It comprises the proceedings of a meeting of the Prediction Study Group of the American College of Neuropsychopharmacology held in December 1968. The object of the research projects described in this book is to predict which patient will respond to which drug. A typical study follows this recipe: take about 500 patients, measure them on about seventy-five variables, clinical and demographic, treat them with one or more drugs and assess the outcome. Use complicated statistics to see which variables influence the outcome. The results are not only indigestible but only about twenty per cent of the outcome variance can be predicted, rendering the exercise unproductive. One reason for this failure may lie in the neglect by the investigators of pharmacological factors. Only in the excellent introductory chapter by S. Gershon is attention drawn to the marked variation between patients in plasma levels of many psychotropic drugs. The reluctance of many investigators to use pharmacological techniques in clinical studies will perpetuate the isolation of psychopharmacology which will be unfortunate as such techniques promise to rationalize our clinical use of psychotropic drugs.

MALCOLM LADER

Clinical Enzymology

Mattenheimer's Clinical Enzymology: Principles and Applications. By Hermann Mattenheimer. Pp. xiv+168. (Ann Arbor Science: Ann Arbor, May 1971.) $14.75.

Enzyme Synthesis and Degradation in Mammalian Systems. Edited by M. Rechcigl. Pp. xvi+477. (Karger: Basle, Paris and London. Distributed in the USA and Canada by University Park: Baltimore, 1971.) 90 Sw. francs; £9.50; 90 DM.

MEASUREMENTS of the activity of enzymes in blood serum constitute one of the most important ingredients in the explosive growth of clinical biochemistry. Beginning as a series of random observations of changes in the levels of a few serum enzymes in a limited number of diseases, diagnostic enzymology now offers systematic data of wide clinical application, based on rational hypotheses about factors which influence the levels of enzymes in the blood: this is particularly so with regard to the leakage of intracellular enzymes which accompanies acute tissue damage. However, efforts to assess the nature of intracellular events by direct measurement of enzyme activities in tissue samples have made slower progress, mainly for methodological reasons, except in the demonstration of inherited conditions which affect the metabolism of red blood cells and in certain other metabolic abnormalities. The growing importance of clinical enzymology has been accompanied by the appearance of textbooks which aim to codify and to rationalize the mass of data which appears yearly in the medical literature, and to guide clinicians and clinical biochemists in the scientific basis, selection and interpretation of enzyme tests. Mattenheimer's book fulfils this function, and in addition offers some differences in content and emphasis from other books in this field. Thus, only one chapter of twenty-five pages is devoted to interpretation of enzyme tests on blood plasma, with a further eight pages on enzyme tests on urine. The other eight chapters are devoted to brief descriptions of principles of enzymology, metabolic pathways, enzyme–hormone interactions, protein synthesis, inborn errors of metabolism, and the enzymology of cells and organs (two chapters). The last two topics, with their implications for future developments, form perhaps the most interesting and original part of the book. The subject of the last chapter, methods of estimation of enzyme activity, could have been left to specialized laboratory handbooks.

This wide range of topics inevitably results in superficial treatment of some; for example, protein synthesis and biochemical genetics, and intermediary metabolism, but the value of the book lies mainly in its correct emphasis on the unity of clinical and non-clinical enzymology. There are a few errors and omissions: alkaline phosphatase activity is probably not decreased in the intestine in hypophosphatasia (page 99); the statement that bone metastases of cancers other than prostatic carcinoma are not accompanied by elevated plasma acid phosphatase (page 128) is incorrect, and in the discussion of inborn errors of metabolism, some reference to lysosomal enzyme deficiencies in lipid storage diseases and the role of amniocentesis in prenatal diagnosis would have added an up-to-date touch. These minor criticisms should not, however, deter those concerned with clinical enzymology, especially clinicians, from reading the book.

Interpretation of enzyme activities in organs or blood is related fundamentally to a knowledge of rates of enzyme turnover and of factors which influence them. *Enzyme Synthesis and Degradation in Mammalian Systems* is a valuable collection of twelve reviews of research on these topics, particularly by reason of its mammalian, rather than microbiological, emphasis. The chapters vary in length from fifteen to sixty pages, but all are well written and are supported by extensive lists of references: these include a number dated 1969, so that the picture is essentially contemporary. The relative value of individual articles will be assessed differently by different readers, depending on their own familiarity with the topics discussed. However, the long chapter by Rechcigl on enzyme turnover is particularly comprehensive, and brings out clearly the prevailing state of mystery with regard to mechanisms of enzyme breakdown. The apparently highly selective nature of the processes involved in enzyme turnover is well exemplified by the case of lactate dehydrogenase isoenzymes (reviewed here by Vesell and Fritz), in which rates of synthesis and degradation in two catalytically and structurally similar proteins are found to differ widely within a single type of cell. Gelehrter argues cogently against the uncritical translation to mammalian systems of data on the induction of enzymes in micro-organisms, while chapters on nutritional (Freedland) and hormonal (Rosen and Mulholland) influences on enzyme activity, and its rhythmic variation (Fuller), also emphasize the complexity of enzyme control in the whole animal.

These chapters, and the others in this collection, constitute a stimulating volume but, in view of the problems which await solution, one which also cautions against over-optimism. Perhaps, however, only a few years will elapse before reviews of this nature will need to warn against too ready an extrapolation of mechanisms established for rat liver to processes of human health and disease.

D. W. MOSS

Nuffield Texts

Nuffield Science Teaching Project: Advanced Science (Chemistry). *Special Studies* (ed. J. G. Raitt): Food Science. Pp. 150. 90p. Biochemistry. Pp. 150. 90p. *Programmed Text*: *Ethanol and other Alcohols.* By Erica Glynn. Pp. 137. 60p. *Standard 8 Film Loops*: *Born–Haber Cycle; Hydrolysis of Bromoalkanes; Rates of Reactions.* £6.30 each. Penguin Education, Penguin Books Ltd; Harmondsworth, Middlesex.

THIS latest batch of Nuffield A-level chemistry materials maintains the generally high standard of its predecessors. *Food Science* is clear, direct, and stimulating; I learnt a great deal from it. The social aspects of the study are never kept in the background, and a major aim of the book is stated on page 3: ". . . The broad outline of the subject may help (readers) to consider how an understanding of the chemistry, physics and biology of foods can contribute towards the improvement of the health and well-being of mankind, and towards solving the problems of the shortage of food in the world". Nonetheless, the chapter on the world food problem fails to go far enough in posing the intense problems which must be faced within this century. The book is particularly good on technology, and there is an excellent outline of the processes occurring in foods during treatment and storage. The authors fire a salvo at macrobiotic food fanatics (page 95) in the course of an interesting chapter on food legislation and public health. A-level readers may find some of the chemistry tough going (for example, the browning reaction on page 56); but the book concludes with a good practical section.

Biochemistry seems to be written in a less easy style, although it gets much better as it goes on. It starts badly with some facile comments on DNA (page 1) which include a disturbingly naïve paragraph on genetic engineering, and a silly question about the Golgi apparatus (page 9). Assumptions are made about the "vocabulary" of A-level readers, particularly in the section on metabolism; here, Lehninger's diagrams are not sufficiently clear to give confidence to those treading these complex pathways for the first time. Able pupils may wonder why (as in *Food Science*) monosaccharide hexoses are always represented by Haworth structures rather than in the chair conformation, and why the stereochemistry of, for example, cholesterol and gibberellic acid is not shown. Fig. 49 has a mislabelled axis; the caption for muscarine is mysteriously transposed from page 51 to an innocent amylopectin chain on page 53.

The book has several excellent sections, especially on medical aspects. The agricultural section is fine, but the dangers of pesticide abuse are not mentioned. The chapter on biochemistry and commerce is compelling, particularly the section on sewage disposal. (I was intrigued to see a photograph of our local rural district council's activated sludge plant.) The experimental investigations look good.

Ethanol and other Alcohols is a straightforward, highly competent programmed text containing a large proportion of practical work.

The film loops are much better than their O-level counterparts. They limit themselves to one topic and work at it thoroughly. The accompanying notes are very lucid. *Rates of Reactions* provides a convincing demo using the Dainton/Fisher ping-pong ball machine. *Hydrolysis of Bromoalkanes* makes good use of models, and the diagrams in the *Born–Haber Cycle* are bright and clear. My only criticism is the cost of these films. MARTYN BERRY

X-Ray Diffraction

Interpretation of X-ray Powder Diffraction Patterns. By H. Lipson and H. Steeple. Pp. viii+335+3 plates. (Macmillan: London; St Martins Press: New York, May 1970.) £4.

THE textbook *Interpretation of X-ray Diffraction Photographs,* by Henry, Lipson and Wooster, itself the distillation of much teaching experience, has been a standard reading and reference work for many generations of undergraduates and of postgraduates learning to use crystallographic techniques. But since it was first published the subject has developed enormously and new methods, both experimental and interpretative, have become both available and standard.

To have revised the original book would have been to produce a textbook both too unwieldy and too expensive; and the decision was therefore made to rewrite the book in separate parts, making each complete in itself. For the practical study of many important solid materials that do not form single crystals of adequate size for individual examination, or that can only be obtained as a mass of randomly oriented crystallites less than, say, 10 μm in individual size, powder diffraction methods are essential. Moreover, X-ray photographic methods have been supplemented or, for some purposes, replaced by counter-diffractometer techniques including those of neutron diffraction. To the metallurgist and the solid state physicist, the geologist and those concerned with phase diagrams of all kinds, or simply with the identification of unknown materials, the powder diffraction pattern is invaluable. The technique is, in general, non-destructive and requires less than 1 mg of material; or it can be used with massive specimens *in situ.* It is therefore of the utmost practical importance. The preface implies that this is an undergraduate textbook: but it is much more than that.

Nevertheless, it is aimed in the first place at undergraduates and it begins therefore at the beginning, with crystal lattices and crystal symmetry, with the geometry of X-ray reflexion and the nature and production of X-rays. Some of the diagrams in this section are less than satisfactory. Fig. 3.2 would give a student a very weird idea of the spectrum from a copper target run at 35KV, and fig. 3.6 that of both the intensity of radiation and absorption of very short wavelength X-rays. These are followed by methods of recording and measuring powder patterns and of interpretation, with descriptions of standard and special-purpose equipment. It is a pity that although measurement of coefficients of thermal expansion is mentioned as an application, nothing is said about the absurdity of claiming to make accurate dimensional measurements (a limit of one part in 100,000 is mentioned) unless the temperature of the specimen, and not merely the ambient temperature, is measurable and is recorded.

The chapters on applications make one wish for more.

A new feature is the section of undergraduate problems (with solutions), but there follow the useful appendices and tables, with subject, references and author indexes that will certainly extend the use of the book beyond that of the undergraduate. KATHLEEN LONSDALE

(This review was completed by Dame Kathleen Lonsdale before she died earlier this year.)

Analysis by Activation

Principles of Activation Analysis. By Paul Kruger. Pp. xi+522. (Wiley: New York and London, August 1971.) £11.75.

RADIOACTIVATION analysis, a by-product (or should it be a spin-off to be really up to date?) of research in nuclear science, is now well established in its own right as an important tool in science and technology. In this book, Kruger discusses some of the applications in his final and longest chapter and devotes a good fraction of it to the analysis of trace elements, an appropriate choice in view of the very high sensitivity of activation analysis. In this day and age, industry and the environment were almost bound to be mentioned, and they are, but sensibly and with reasonable detail. Oxygen in metals, the logging of oil wells and on-line techniques are the main examples from industry; here, as in the other fields which I do not have the space to cover, the examples are clothed with extensive numerical information.

It is important for materials analysts, particularly those with a background in nuclear physics, to realize that the nucleus is not the only part of the atom capable of emitting identifying radiations, as I am sure the optical and X-ray spectroscopists would quickly point out. With this in mind, I was pleased to see that Kruger's section on trace element analysis includes a comparison of activation analysis with other methods; the electron probe is not among the others but, even so, the reminder to think broadly is there.

These comments have arisen just from Kruger's final chapter, but what of the rest of the book? The three chapters on the practices and limitations of activation analysis and on radiochemistry, which together form more than a third of the whole, are thorough and should be very helpful to the serious student of the subject. How to select the stimulating radiations, how to use the stimulated ones, whether to include chemical methods, how computers can help—these are the broad issues and in each case there is enough information to satisfy the budding professional. Here he can learn about the complexities of gamma-ray spectra, the problems of spectral stripping, the ways to deal with interfering reactions and a number of other features, and at the end of each chapter he has a few problems to sharpen his teeth on.

This, then, is a book with much useful information, and it is elegantly produced with clear diagrams and tables, but the cost is high for the individual buyer, at least in the United Kingdom. There is no doubt that half the book is well worth half the cost, but less introductory material and a lower total cost would have been a better balance, in my view, because this would have made the book more widely available. After all, Kruger's own excellent bibliography makes it clear that there are already several texts covering this first part of the work. Moreover, cuts in this section could have removed the few slips and ambiguities which are there (resonance scattering of neutrons is not synonymous with inelastic scattering; the relationship between thermal neutron fluxes and fast neutron yields is not as simple as implied; a conventional neutron flux, not the one defined, must be used with tabulated cross-sections to obtain reaction rates; in a Maxwellian distribution at room temperature, 0.025 eV is the energy associated with the most probable speed, not the most probable energy).

CORRESPONDENCE

Italian Science

SIR,—In Italy, research is almost completely in the hands of the National Council of Research (CNR), founded by Mussolini on November 18, 1923 (see *La Ricerca Scientifica*, 1945, p. 108). According to OCSE's experts, the CNR can be compared—as far as its juridic nature is concerned—to "an institution with a corporative nature, comparable with those professional orders which have multiplied during the fascist period". At present all financing has been suspended, and many applications have been rejected, even when some months ago it seemed that they had been approved. As for the applications which have been approved, the funds are still to be found on the budget of 1970 and some say that money for the research going on at present will not be paid until next spring. Young scientists and technicians are therefore obliged to abandon the universities, and projects (some international) must be cancelled in our programmes (supposing one may speak of "programmes" in Italy). And unfortunately this is not the first time we have had serious administrative trouble, though the CNR has at its disposal more employees than research workers.

One example is that of the International Biological Programme (or IBP), which for us was the first timid approach towards ecology, more especially productivity: whereas in other countries the IBP has seen and is still seeing beautiful research, which will go on until 1972, in Italy they say it is over. Whereas abroad many contributions have been published in the field of IBP, here there has been a very poor production. Even the results of the exploration of the small Italian islands, included in the CT programme of IBP, are extremely poor.

This contrasts strongly with the results Italian scientists had achieved in the field of the International Geophysical Year (1955), only 10 years after World War II. We cannot help thinking therefore that our Government's scientific policy is fundamentally very bad.

Useless to say that this has been well known abroad for several years: suffice it to quote Di Ferrante (*Science*, **161**, 451; 1968), Consolazio (*ibid.*, 133; 1968), Greenberg (*ibid.*, **167**, 1706; 1970), and Survey of Science in Europe (*Nature*, **226**, 1016; 1970) who give a very clear and exact description of Italian scientific policy, especially in calling the members of CNR "self serving advisers" (Di Ferrante, p. 451). We must not forget, however, that already in 1955 a member of CNR, Professor Di Mattei, had made a very clear critique of its policy, in which he says (*La Ricerca Scientifica*, **25**, 2372; 1955) "the Committee (for Biology and Medicine) has over all limited itself to a mere paternalistic distribution of the funds it had at its disposition, and has not confronted the great scientific problems which should have been the highest task of its financial policy".

What our responsible men are not able to do is to split *completely* the research in the universities (which are entirely state entities, depending on the Ministry of Education) and that in the CNR centres (which depend on the Presidence of Ministers), keeping two independent budgets, with no interchange or osmosis possible between the two. The full separation of powers and of men would be particularly necessary in a country such as Italy, which is famous all over the world for its "camarillas", mafia, "Baronie", clientelism, and so on. Of course the stronger the relationships between university and CNR, the easier the clientelism between the "owners" of CNR and the university institutes, which today depend for research completely on the former because practically all the members of CNR (presidents of committees, sub-committees, work groups, sections, and so on) are also professors in the chair at some university. With the last events of the CNR, the fear that all of us (university workers) have to be turned in post-lyceum teachers instead of research workers is stronger and stronger and quite justified. On the other hand, the political situation of the country (see a series of articles by P. Nourry and P. Bois in *Le Figaro*, the last of which was published on September 22) does not permit any sort of optimism in this field.

Yours faithfully,

GIORGIO MARCUZZI

Suckling Etymology

SIR,—In his letter (*Nature*, **233**, 73; 1971) Mr Spratling complains that a communication[1] which several co-signatories and I sent to you some 20 years ago has been the cause of the confusion he has recently experienced in fairly extensive reading on the topic of suckling. We are apparently to blame because we used the verb "to suckle" in a manner contrary to the usage of Shakespeare and of that found in the Bible.

English usage never stands still. It is nearly 300 years since the verb "to suckle" began to be used to denote the activity of the young as well as that of the lactating mother. This extension of meaning has caused ambiguities. It was because of this long-standing ambiguity that the signatories of the letter, who were then all working in the field of lactational physiology and well aware of the difficulties that could arise, suggested that it might be helpful if authors of scientific papers were to restrict the use of this verb to denote only one activity and since its commonest usage in contemporary papers was with reference to the activity of the young we suggested that it be so restricted. Mr Spratling is, of course, equally entitled to suggest that the meaning be restricted to the activity of the mother provided that he indicates, as we did, that he uses the word in a restricted sense. To imply, however, that his choice is the only correct usage is, at the present time, nonsense. He should get an up to date dictionary and put Shakespeare on the shelf.

In Mr Spratling's description "the calf sucks the cow" the use of the verb "to suck" is unfortunate, not in this instance because of any change in usage since Shakespeare's time but because there have been some advances[2] in our understanding of the process whereby the young ruminant acquires milk from the udder of its dam. The movement of the suckling's tongue against the hard palate exerts positive pressure on the teat, stripping the milk from it in a manner similar to that of the fingers of the hand milker, suction being a non-essential component of the process. Only the milking machine which obtains milk from the cow solely by the creation of a partial vacuum may, I think, truly be said to suck the cow.

Yours faithfully,

A. T. COWIE

British Diary

Saturday, October 16

Unemployment Among Scientists and Technologists (10 a.m.–6 p.m.) British Society for Social Responsibility in Science, at the Harkness Hall, Birkbeck College, Malet Street, London WC1.

Tuesday, October 19

Extra-Sensory Perception: Fact or Fallacy? (1.30 p.m.) Dr A. J. Ellison, University of London, at Queen Mary College, Mile End Road, London E1.

Insight, Not Numbers (5.30 p.m.) Professor P. A. Samet, University of London, in the Chemistry Auditorium, University College London, Gower Street, London WC1.

New Techniques for the Determination of the Nutritive Value of Feeding Stuffs for Ruminants (10.30 a.m.) Society of Chemical Industry, Agriculture Group, at 14 Belgrave Square, London SW1.

Problems of Large Power Stations (7.30 p.m.) Institution of Chemical Engineers, jointly with the Institution of Mechanical Engineers, at the University, Nottingham.

The Tectonic and Depositional History of the Eastern Equatorial Pacific During the Cenozoic (5.30 p.m.) Professor Tj H. van Andel, University of London, in the Collegiate Theatre, University College London, Gower Street, London WC1.

Vinyl Resins in Surface Coatings (7 p.m.) Mr D. J. Silsby, Oil and Colour Chemists' Association, at the Pendragon Hotel, Southsea, Hampshire.

Wednesday, October 20

Application of Satellite Relayed Communications to Civil Aviation and Maritime Use (6 p.m.) Institution of Electronic and Radio Engineers, at 9 Bedford Square, London WC1.

Biomedical Research and the Chemist—a View and a Prospect (5 p.m.) The Rt. Hon. the Lord Todd, FRS, at the Royal College of Physicians, 11 St. Andrews Place, Regents Park, London NW1. (Merck Sharp and Dohme Research Laboratories Scientific Lecture.)

Computer-Aided Design in Electronics (5.30 p.m.) Mr P. E. Trier, Institution of Electrical Engineers, at Savoy Place, London WC2.

Developments in Water Based Surface Coatings (7.30 p.m.) Mr A. J. Becalick, Oil and Colour Chemists' Association, at the Carlton Hotel, North Bridge, Edinburgh.

Electronic and Radio Needs for Light Aircraft (6 p.m. discussion) Royal Aeronautical Society, at 4 Hamilton Place, London W1.

Engineering for Nuclear Power (10 a.m., Mr J. C. C. Stewart, Dr D. F. Seymour) Dr Gordon Brown and Mr P. H. W. Wolff, in the Faculty of Applied Science, University of Nottingham. (Bulleid Memorial Lectures.)

How to Survive on the Planet Earth (6.15 p.m.) Dr A. Peccei, United Kingdom Automation Council, in the Council Chamber at the Confederation of British Industry, 21 Tothill Street, London SW1.

Martin Lister (6 p.m.) Mr S. Peter Dance, Society for the Bibliography of Natural History, in the Men's Staff Common Room, University College London, Gower Street, London WC1.

Speech Scrambling and Security (7.30 p.m.) Mr R. C. French, Institution of Electrical Engineers, at the Mullard Research Laboratories, Redhill, Surrey.

The Training of Sandwich Course Students on Degree Courses Containing Options in Analytical Chemistry (3 p.m. discussion meeting) Society for Analytical Chemistry, Education and Training Group, at the Thames Polytechnic, Woolwich, London SE18.

Thursday, October 21

Agricultural Productivity in the Third World (8.15 p.m.) Professor Sir Joseph Hutchinson, University of London, at Wye College, near Ashford, Kent.

Pollution (7 p.m.) Dr R. B. Brown, Oil and Colour Chemists' Association, at the Beech Tree Hotel, Maxwell Road, Beaconsfield, Bucks.

The Evolution of the Geosyncline Concept (5.30 p.m.) Professor Ken Hsu, University of London, in the Collegiate Theatre, University College London, Gower Street, London WC1.

What Strings on Medical Research? (5.30 p.m.) Sir John Wolfenden, University of London, in the Beveridge Hall, Senate House, London WC1.

Friday, October 22

The Distance Scale of the Galaxy (9 p.m.) Sir Richard Woolley, FRS, Royal Institution, at 21 Albemarle Street, London W1.

The Paleomagnetism of Marine Sediments (5.30 p.m.) Dr N. D. Opdyke, University of London, in the Collegiate Theatre, University College London, Gower Street, London WC1.

The Quenching of a Diazo-Chromophore Fluorescence by Aliphatic Hydrocarbons (1 p.m.) Royal Institution, Photochemistry Discussion Group, at 21 Albemarle Street, London W1.

Waiting for the Other Shoe to Fall

By now, it is clear that the British scientific community is at once discreet and patient. For several weeks, there has been clamour for the publication of the report of the committee under Sir Frederick Dainton which is supposed to have worked out a strategy for the development of public support for university research for the next several years. To less innocent or scrupulous people, it may seem remarkable that those who know what the Dainton report consists of, and who are beating the drums for its publication more loudly than others, have not chosen simply to say what they think this now secret document contains. Is there, by any chance, a possibility that protest against the failure to publish so satisfies the wish to believe that the bureaucracy is malevolent that attention has been diverted from the alleged objective to see that information is put about ?

In practice, it is not very hard to guess the general drift of what the several participants in the game of reshaping public policy on science are likely to be saying. A year ago, when Sir Solly (now Lord) Zuckerman grabbed the tiller of the ship of state from time to time, it would have been easy to predict that the research councils would be swept away, with the Agricultural Research Council being transferred to the Ministry of Agriculture, the Medical Research Council to the Department of Health and Social Security and the Natural Environment Research Council to some place in which it would be even less easily identified. Sir Frederick Dainton has a more modest task—his committee has been asking how the universities and the research councils should respond to the growth which there has been and will be in higher education. What will happen to the character of university research if the funds available grow less quickly than the numbers of undergraduates ? Will the life of an academic become much more that of a teacher than a researcher ? What will be the relationship between the research councils and the University Grants Committee ? Is it sensible that the research councils should be the chief arbiters of the pattern of academic research ? There is no doubt that the Dainton report, when it finally emerges, will applaud the way in which the research councils have recently adopted with enthusiasm the policy of selectivity and concentration for which the Science Research Council paved the way. At the same time, the Dainton committee will be found to be urging that academics should become increasingly reconciled to the belief that research is a privilege and not a necessary accompaniment of a job. What the Dainton committee will say about the research councils and the relationship between them is less clear, although there seems no doubt that the Dainton report is a moderate document, pleading that research councils with responsibilities in applied research should devise ways of responding more sensitively to the interests of their chief customers.

On the relationship between the research councils and government departments and the universities, it has for more than half a century been conventional to recite an approximation of what is known as the Haldane principle, that in the conduct of basic research there needs to be some tension between those who carry out the research and those who in due course make use of it. What this implies, for example, is that there is some virtue in an arrangement under which the Agricultural Research Council (for example), responsible for basic research in agricultural science, should be managed separately from the chief users, farmers and their shepherd, the Ministry of Agriculture. The trouble, of course, is that a doctrine like this, invented in the middle of the First World War, cannot easily be expected to be valid both then and now, when the character of basic research, the relationship between basic research and applied research, and the scale on which the scientific enterprise is carried out have been radically transformed. Thus it has become convention to the managers of research policy within the government to proclaim that "Haldane is dead". To Sir Solly Zuckerman, Haldane was indeed quite dead. Both Sir Frederick Dainton and Lord Rothschild may in their different ways have more moderate versions of this theme —Haldane may be mostly dead.

In the last resort, of course, the future pattern of British scientific research will depend much more on what the government thinks of what Lord Rothschild has recommended than on the Dainton report, published or unpublished. Which way is the wind blowing ? The Rothschild inquiry and the Dainton inquiry overlap only at the edges, which is not to say that it is not a misfortune that the Rothschild inquiry has been confined to civil science in the strict sense—even the civil functions of the defence laboratories remain secrets to themselves alone. On the view that Haldane is dead or mostly dead, the research councils must necessarily change their relationship with government departments, and nobody should be surprised if in due course they find themselves compelled to earn at least some of their support from their customers. To be sure, the chances are that any changes which come about will be gradual. And while it is at least conceivable that the research councils responsible for agriculture and medicine could establish such a powerful claim on the interests of the corresponding ministries that they would be able to continue a useful life—perhaps even a more rewarding life—even those who fancy outlandish bets would not give much for the chances that the Natural Environment Research Council will be able to make a decent living for itself in that hard world.

In all this speculation about the future pattern of scientific research in Britain, it is possible to identify several simple truths, some of them at first sight contradictory. First, it is curious how much the reorganization now in prospect reflects opinions which have somehow become widely accepted—one of the mysteries of 1971 is that universities have reconciled themselves to a rate of growth through research expenditure which is less rapid in real terms than the rate of growth of the student population, and have done this without a murmur, for example. From this point of view, the changes which the government may eventually recommend may seem less like acts of policy than historical necessities. Second, not all the talk of the need to reorganize research expenditure in Britain has yet touched the question of how policy on defence research should be worked out. Third, there is a danger that enquiry into the management of research policy will become a substitute for policy. In the past ten years, there has been a continual struggle by the government and its advisers to optimize the mechanism for dealing with research in Britain. It is entirely possible that the time has come to leave it alone for a while.

Technology Assessment has a Long Arm

THE ministers for science from the member nations of the OECD seem to have had a useful meeting in Paris last week and, although these representatives of European governments are still shadow-boxing with each other as becomes political intervention in a dangerous field, they seem now to have got the hang of how to make a public statement of policy. The hope is that they will soon also learn how to make effective policies, for there is an urgent need that some means should be found of giving the OECD a framework within which to do sensible things.

The difficulty with last week's meeting was the concept of technology assessment (see page 512), invented originally by Mr Harvey Brooks of Harvard University. The trouble is that technology assessment is too seductive a concept for politicians to resist. The phrase itself implies two things—solicitude for technology and anxiety that the consequences of technology should be predicted. In other words, technology assessment appeals both to technologists and to those who are suspicious of technology. At the meeting in Paris last week, the ministers appear to have applauded themselves for devising a communiqué that says such things as "more basic knowledge is necessary to solve the increasingly complicated problems of modern society", which holds that "the growing importance of social objectives requires increased support for the relevant social sciences, including research" and at which ministers are said to have "agreed on the need to stimulate further improvements in the innovation process if the results of research and development are to have the maximum diffusion in society". It is true that the spirit of a successful conference is rarely embodied in the communiqué issued at the end, but on this occasion platitude seems to have had a field day.

What should the ministers of the OECD do? It is not, after all, that there are no jobs to be tackled. It is tempting to think that a call for "intensified scientific and technical cooperation" will serve some purpose, but how is the cooperation to be carried out, in what fields, by whom, and which governments will take the initiative? It is tempting to think that outsiders will be stimulated by the declaration that "a major task for science policy will be to assess the adverse and beneficial consequences of technological development and to foresee scientific and technical trends", but who are the people who will also foresee the consequences of now familiar practices, such as the dumping of untreated sewage into freshwater lakes and rivers? Which governments will accept the logic of those discoveries and require their taxpayers to provide sewage treatment plants? The trouble is that technology assessment is not merely a balm for the consciences of those who think that technology needs watching but a defence for those who hope that, if enough people worry about problems which do not yet exist, nothing need be done to tackle the problems which already abound.

Whose Head is in the Sand?

A WEEK from now, it should be apparent whether or not Britain will be joining the European Communities in 1973. The debate now under way in the House of Commons will finish on Thursday with a vote that will decide whether the British government is strong enough politically to go ahead with its intentions to accept membership on the terms which have been negotiated, at least in outline, over the past few months. It is shrewd of Mr Edward Heath, the Prime Minister, to have said that members of his own party will be allowed to vote as their inclinations guide them. He has very little to lose and quite a lot to gain by taking this course. Even so, the outcome of the proceedings in the House of Commons remains uncertain. Mr Heath will get his majority, but it remains to be seen how large it is or, perhaps more important, how it is constructed and thus how strong it will appear to outsiders. This is why it may not be entirely out of place to recall that the present difficulty about British membership of the European Communities stems almost entirely from the way in which the leadership of the British Labour Party, with one or two exceptions, has gone back on its own commitment to membership.

The shabby way in which this has been done is a conspicuous scandal. There is at present no reason to suppose that Mr Harold Wilson's government would have been able to negotiate better terms for membership than those agreed last summer in Brussels, and no reason to expect that the previous Labour government would not have accepted them. The argument which now prevails that the terms could have been better is hard to deny, but to use this complaint as a serious criticism of the arrangements now proposed is a little like the way in which would-be members of golf clubs might complain that they will join only if the annual subscription is made cheaper. It is equally unconvincing now to complain that the policies of the European Communities will prevent the British government from pursuing its own schemes for regional development and the like and will thus infringe British sovereignty—for one thing, there has never been any doubt that the Treaty of Rome would inhibit the freedom of governments to bolster up uneconomic parts of their economy so as to increase their competitiveness artificially, but equally it is well established that the European Communities as a whole have a responsibility for precisely the kinds of regional problems which the Labour Party is now saying will be neglected.

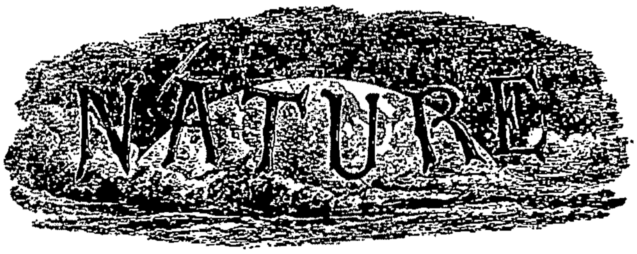
The most alarming contrast between the position taken by Mr Harold Wilson in his previous incarnation as Prime Minister and that which he now holds is that his old brave words about technology in Europe have been almost entirely stifled. In all the declarations of the past few weeks, nothing has been heard from Mr Harold Wilson or his close colleagues of the opportunities for technological collaboration between members of the European communities. Yet many will still recall the Guildhall speech in which he painted a glowing picture of the opportunities that the enlargement of the Common Market would provide. At that point, there were schemes by means of which European governments, the British prominent among them, would collaborate on technical projects such as the development of aircraft or large computers and common research and development in telecommunications. The first principle seemed to be that the combined resources of the nations of Western Europe would be better able to keep up with the pace of technical development elsewhere, the United States, for example. The second principle, chauvinistic perhaps, was that Britain had invested such comparatively large sums in research and development that extra skills had in the process been acquired, with the result that British expertise in technological development might be regarded as a kind of dowry, helping to smoothe the way for membership.

For what it is worth, Mr Wilson's first vision was far too rosy, just as his present view appears to be too misanthropic. In the past twenty-five years, there has been plenty of evidence that the success of technological development must depend on the existence of a market. Research and development will not bring prosperity unless the products are commodities or machines that people are prepared to buy. Most European countries have by now a lengthy catalogue of research and development programmes which have turned out differently. Even now there are devices such as the Concorde which may never be commercially viable and which may even fail to provide a platform on which more advanced (and saleable) technical developments may be founded. In Mr Wilson's earlier talk of the wonders of European technology, there was too much tendency to regard research and development as a kind of magic wand. But equally, there are great benefits to be derived from a state of affairs in which the developers of new products are able to spread their initial costs over a market the size of that which now exists in Europe. Indeed, once the economic integration of Europe has gone a little further, there should be a rapid stimulation of research and development as manufacturers begin to recognize that they can afford to pay for it. By contrast, if Britain were to remain economically detached from the mainland, as Mr Wilson now appears to think it should, the difficulties that haunted his government and its predecessors in planning for public support of technological development will persist. Time and again, governments will find themselves investing too little in huge and ambitious undertakings. The total cost of publicly supported research and development will remain a large proportion of the total, but both the sponsors and the research managers will be left with the impression that important work is being skimped. Even if Mr Wilson himself is not any more aware of how European economic integration offers opportunities for this kind of development, his right-hand man, the syndicalist Mr Anthony Wedgwood Benn, should have enough experience from his spell at the then Ministry of Technology to know how important it is to rationalize the planning of research and development in Britain.

There are, of course, lessons to be learned in mainland Europe on this same theme. Luckily, the wind now seems to have gone out of the sails of the plans for mounting collaborative research programmes in important fields such as telecommunications. Instead, there seems to have grown up a proper respect for the importance of the customer in the chain of technological development. This week in Brussels, it is clear that there will be a hard fight over the research and development programme on nuclear power put forward by the European Commission in the summer. By now, it seems to have been acknowledged that the Joint Research Centre at Ispra, the most tangible and perhaps the most embarrassing survivor from Euratom, will have a sensible programme of research in the next three years. There is a budget for covering fundamental work in nuclear energy, some attempt to make a close study of the biological effects of radiation and some modest work in the environmental sciences. The question now to be decided is how the European Communities should support research and development of benefit to the nuclear engineering industry.

---

100 Years Ago



WE have to record the death, on Saturday last, at the age of seventy-nine, of Mr. Charles Babbage, the eminent mathematician and mechanician. The most important events of his life, as well as some of the eccentricities of his character, are familiar to the public through his autobiographical volume, "Passages in the Life of a Philosopher." Born in 1792, he entered Trinity College, Cambridge, in 1810, and was transferred to St. Peter's the following year. At his B.A. degree he did not take honours in mathematics, not having specially pursued that subject of study as a student, and was understood to have been disappointed at not being elected a fellow. In 1828 he was however elected Lucasian Professor of Mathematics at Cambridge, a position once held by Sir Isaac Newton. He published no less than eighty volumes, but his claim to public notice rested chiefly on his invention of the Difference Engine, on which he spent immense labour and a large sum of money. Notwithstanding his eccentricities and his failings, Mr. Babbage was a mathematician and an inventor of whom England may be justly proud.

From Nature, 4, 512, *October* 26, 1871

OLD WORLD

SCIENCE POLICY

Technology Assessed

"TECHNOLOGY assessment must not become technology arrestment" is how Dr Edward E. David, President Nixon's scientific adviser, summed up the fourth meeting of ministers of science of OECD countries which took place in Paris last week. Dr David said in London after this meeting that in the seventies the quality of life is going to be a more important consideration than it had been in the sixties.

The two-day meeting discussed three main themes; trends and objectives in science policy in the 1970s, innovation in society and the economy and international cooperation in science and technology. The British delegation was led by Mr J. F. Embling of the Department of Education and Science. At the end of the meeting a joint communiqué was issued by the delegates from the 23 member countries which outlines a considerable change in official attitudes to science and technology.

The text for the conference was the Brooks report on "Science, Growth and Society" which argues that qualitative growth has been sacrificed to quantitative growth and that the risks and benefits of technology should be better assessed (see *Nature*, **232**, 6; 1971). To be sure, the ministers affirmed that "science and technology will continue to be essential elements in social and economic progress in member countries. At the same time . . . science and technology should contribute more fully to the improvement of the quality of life as well as to material well-being, and that the undesirable side-effects of their application should be controlled". Thus the ministers have accepted much of the basic stance of the report, resolving that, while research must be expanded and technological innovation stimulated, it must not be merely for quantitative growth but "to meet social needs such as environmental quality, health, education and urban development"; furthermore effective management and control of technology in the public interest must be established.

The ministers emphasized that the problems society faces are many sided and complex and underlined the need for closer links between economic, social, science and educational policy making at national and international levels. The communiqué also applauds the notion that innovation in the public sector, where market incentives may not be great, may require special measures by the government. They also call for more research into the harmful and beneficial results of new technologies.

The communiqué pays considerable attention to the promotion of cooperation between member countries, particularly encouraging cooperation in fundamental research and in the planning and utilization of expensive facilities, for example high energy physics, by international teams. On the problems of the relations between the developing members of the OECD and their richer counterparts, the ministers considered that more should be done to transfer technology to the developing members and to strengthen their scientific and technological capacity.

The policy statement is radical enough. Dr David pointed out that the fact that people having been talking along these lines for some time may lessen the apparent size of the change in policy, but he emphasized that the meeting represented a "turning point" in the application and control of science and technology.

RESEARCH COUNCILS

Pilot Fish for Dainton

A PATIENT explanation of the way in which university research is at present supported with public money has been provided by a committee of the Council for Scientific Policy under Sir Harrie Massey (*Report of a Study on the Support of Scientific Research in the Universities*, Cmnd 4798, HMSO, £0.45). The document spells out some of the questions which are answered (by all accounts) in the report of the working party under Sir Frederick Dainton, still regarded by the British government as one of those against which the Official Secrets Act is directed, but the committee says that it has not sought to answer them. For that reason, it is inevitable that its recommendations should be somewhat anodyne.

The committee commends the system under which the University Grants Committee and the research councils both help to support university research, with the former "providing the floor of support for research" and the research councils being selective. Forlornly, the committee hopes that the government will recognize the growing cost of research equipment, reckoned to have risen by between eight and eleven per cent in the past twelve years, says that contract research in the universities should be charged for at rates that take full account of overheads and suggests that the research councils should be free not merely to provide equipment or the salaries of operating personnel but any other services which may be needed, buildings for example.

The committee comes down against the so-called handover principle by means of which research projects begun by a research council are transferred to the appropriate university at the beginning of each university quinquennium together with the necessary allocation of funds, and to that extent the report is an echo of what the Science Research Council has already decided to do (see *Nature*, **233**, 298; 1971). The committee also applauds the Science Research Council's policy of selectivity and concentration, saying that it will have to go much further in the years ahead and that, in the process, there will have to be close consultation between the research councils and the universities.

The unanswered questions supposedly tackled by the Dainton committee proper are those of whether university research will be damaged by such accompaniments of the expansion of higher education as a deterioration of staff-student ratios and the shortage of technical support in administration and finance in British universities, the question whether there should be a constant ratio of undergraduates to postgraduates, what balance there should be between different kinds of postgraduate courses and what experiments should be made in varying the length of postgraduate courses as a whole. By all accounts, the Dainton report in its full splendour will be published in the next few weeks.

EMBO

One Bridge More

THE laboratory of the European Molecular Biology Organization will almost certainly be built at Heidelberg. At a meeting last week in Geneva of the European Conference on Molecular Biology (the association of states which will fund EMBO), it was decided to accept the recommendation of the working groups on the laboratory (see *Nature*, **228**, 7; 1970) that the laboratory should be at Heidelberg.

Three firm offers of a site for the laboratory were received, all of them in Germany. (Britain recently decided not to offer facilities at Culham—see *Nature*, **233**, 154; 1971.) Two sites were in Munich, one at Garching and the other at Martins Ried. The first site had the advantage that it is near the plasma physics laboratory (and instrumentation is an important theme in the prospectus of the new laboratory) but in other respects did not seem suitable. The second site, although lacking a physics laboratory, is close to the site where the new laboratories of the Max Planck Institute are to be built; this was at once an advantage in offering immediate temporary accommodation until the EMBO laboratory itself could be built, but a disadvantage in that some people have been afraid that the Max

Planck laboratories might overshadow the EMBO laboratory. Heidelberg, however, is a good choice because there are well developed physics facilities and temporary accommodation can be provided if necessary.

The agreement of the ECMB is no guarantee that the laboratory will be built. First of all, the member states must ratify the agreement to provide the budget. Nine states voted for the resolution (Denmark, Austria, France, Norway, Germany, United Kingdom, Switzerland, Spain and the Netherlands), while Sweden abstained. Israel was not present at the meeting and Greece and Italy cannot vote because the Italian government has not yet ratified its membership. Belgium, although it contributes indirectly, is not entitled to a vote.

The next step will be for a revised budget to be produced by the ECMB by December and decisions about the laboratory should finally be agreed by April 1972. Work can go ahead to establish the laboratory as soon as EMBO is sure that funds will be forthcoming ; this means that no action will be taken until 70 per cent of the budget is assured. It seems likely that agreement by sufficient states will take about a year, so that arrangements for temporary accommodation and for building the new laboratories cannot be made until April 1973. (In addition to its assessed contribution to the ECMB, Germany has offered some £1.2 million to help with capital expenditure.)

No director of the laboratory has yet been appointed, but Dr John Kendrew, the widely tipped choice for the job, has been appointed project leader. In that capacity, he will be responsible for organizing the laboratories during their opening stage ; this is of indeterminate length and, at some time after the laboratory is functioning, a director will formally be appointed. If plans do not fall too far behind schedule, some sort of grand opening ceremony of the laboratory can no doubt be expected in 1976.

NOBEL PRIZE

Cyclic AMP Recognized

The award of a Nobel Prize for Medicine to Earl Sutherland, Professor of Physiology at Vanderbilt University School of Medicine in Tennessee, will be universally acclaimed among biochemists. Professor Sutherland, who is fifty-five and has been studying hormone action for twenty-five years, is the forty-third American to receive the award, now worth £36,000. This is the first time in ten years that the prize has not been shared. A generation of biochemists had now been brought up on Professor Sutherland's theory of hormone action, which stems from his discovery in 1957 of what is now known to be a ubiquitous biological molecule, cyclic AMP.

Professor Earl Sutherland.

Sutherland's group were in 1957 trying to find out how the hormones glucagon and adrenaline mobilize glucose from glycogen, its storage form in the liver. When they added either hormone to an extract of liver cells, the production of this unknown monophosphate derivative of adenosine was easy to detect. Biochemical analysis subsequently showed this to be 5′, 3′ adenosine monophosphate, with the phosphate making an inelegant and unexpected bridge between the third and fifth carbon atoms of the ribose component.

Much more refined kinetic studies revealed that the hormone-induced increase of cyclic AMP in liver cells occurs before glucose mobilization is apparent, which strongly suggested that cyclic AMP is an effector, rather than a by-product, of the mobilization process. It was on the basis of these extensive studies that Sutherland proposed his novel concept for the molecular basis of hormone action. Glucagon or adrenaline acts to correct low levels of blood glucose by stimulating the enzyme adenyl cyclase of liver tissue to convert ATP to cyclic AMP. Cyclic AMP then behaves as a "second messenger" within the cell to promote the release of free glucose. In a complex series of reactions, cyclic AMP causes the conversion of the enzyme glucose-1-P phosphorylase from its inactive to active form, which breaks down glycogen by pyrophosphorolysis.

More recent work has not only verified this idea but has also shown cyclic AMP to be the second messenger for several other hormones, including those that mobilize lipids from fatty tissues and those that provoke the synthesis of steroids. Because of these and other function ascribed to it, cyclic AMP has become something of a wonder molecule. It is implicated not only in the stimulation of various enzymatic activities, as in glucose mobilization, but also in the control of gene expression both in bacteria and in the cells of higher organisms.

But even as research on cyclic AMP burgeons and new findings continue to change old ideas, it seems that Dr Sutherland's proposal for its action as second messenger stands out as clearly as his discovery of the molecule itself. The practical implications of this discovery are difficult to assess, but one application is likely to be the use of derivatives of cyclic AMP which can overcome deficiencies in certain hormones by stimulating specific functions.

FOOD

Mercury Miscellany

It seems that the average Briton has no need to worry about any mercury he ingests from food. This balm appears in a report issued by the Ministry of Agriculture, Fisheries and Food after a nine-month investigation into the level of mercury in food which was prompted by the ban placed on the sale of tuna fish in the United States last December (*Survey of Mercury in Food,* HMSO, £0.20). The working party finds that the amount of mercury in the average diet of a British person is "extremely low and in most cases barely detectable". The level of mercury in canned and fresh fish and shellfish is also low but higher than in other foods.

Mr James Prior, Minister of Agriculture, Fisheries and Food, wholly endorsed the report last week and added that it had not been possible to identify in Britain any group that had suffered from ingesting mercury. The investigation showed that even with a group of six fishermen, there was not an inordinate amount of mercury in the hair, but blood analysis showed that they had more mercury in their blood than did six control subjects—the fishermen had between 0.01 and 0.03 mg kg^{-1} compared with the control subjects who had at most 0.005 mg kg^{-1}.

Mr Prior has recommended that mercury in food should still be monitored and that other heavy metals—lead and cadmium in particular—should also continue to be monitored. Methyl mercury will get special attention. An implication of the report is that monitoring for mercury will continue at a reduced rate, but special attention will be given to fish caught in coastal waters where the chances of mercury pollution are high.

One of the reasons given for not banning the sale of canned tuna in Britain, as was done in the United States last December, was that the average amount of tuna eaten per person in Britain is only one tenth that of the USA. The report shows that the amount of mercury found in canned tuna in Britain is similar to that found in the United States and of the varieties of foods tested tuna contained most mercury—an average of 0.18 mg kg^{-1} compared with canned salmon that was found to contain between 0.01 and 0.04 mg kg^{-1} of mercury. No detectable mercury was found in flour, cheese, beef, chicken meat, eggs, bacon, ham, rice, sugar, and breakfast cereals while small but detectable amounts were found in cabbage, potatoes, apples, carrots and imported tomatoes (all less than 0.004 mg kg^{-1}).

FRENCH SCIENCE

Budget Plans

from *La Recherche*

WITHIN the next few weeks the French Parliament will be approving the country's research budget for the coming year. This action is significant because 1972 will be the first year of the sixth five-year plan, and will thus be evidence of the long-term intentions towards research.

There has been nothing innovative so far in the method of determining the French research budget, although the *enveloppe-recherche,* or grouped project approach, has been refined. This idea is that most of the sums voted for civil research and development underwritten by various ministries are examined in advance each spring by an interdepartmental group. Thus, the money to be spent on the *enveloppe recherche* in 1972 is in close agreement with the overall *enveloppe* approved for the comprehensive 1971–5 plan.

The total vote for 1972 is 3,848 million francs (almost £287 million) in research programme authorizations. This represents an increase of 15.5 per cent on the year. If this increase appears to be unusual, it is nonetheless quite in line with the minimal projections set forth in the plan. The breakdown of the budget conforms, of course, with the major options set forth in the plan so that, for example, the 54 per cent increase awarded to the Health Ministry and the 46 per cent increase for agriculture reflect the priority being given to research and development in the life sciences. The sums voted for work on pollution and the environment under the aegis of the new Ministry of the Environment increase from 4.2 to 13 million francs (£1 million). The vote for aid to industrial research will also jump sharply while the earmarked appropriations for industry—*l'aide au développement*—are being augmented by an impressive 35 per cent.

Among the research organizations responsible to the Ministry of Industrial and Scientific Research, only the oceanological CNEXO centre will enjoy an increase in its vote (25 per cent). The 1972 sums confirm a levelling out of expenditure at the Commissariat à l'Energie Atomique and a marked braking of the momentum of space research. The space agency, CNES, will be voted a modest increase of 2.3 per cent (581.5 to 595 million francs). There could be a supplementary vote for CNES if the European launcher becomes a reality, but the future of the French space agency is increasingly in doubt.

Operating expenses for research organizations will be raised by about 15 per cent, but there will not be a commensurate increase in the research establishment. In 1971 there were 432 new jobs created throughout the ministries ; there will be 280 next year. At the National Scientific Research Centre (CNRS) there will be 130 new jobs, whereas this year there have been 250. This lack of new blood in the year to come is a difficult problem in France's current scientific research effort.

The situation concerning basic research remains precarious. The 15 per cent increase of operating expenses at CNRS will be devoted largely to adjust compensation in the career development process and to give deserved merit increases to the staff. Elsewhere, the modest sums voted (an 8 per cent increase) for research at the level of higher education is a reversion to past practice. University laboratories face a difficult situation because they depend on the sums voted them directly and in many cases they do not themselves receive support from the CNRS.

So will next year's financing of research amount to nothing more than catching up, to compensate for other, leaner years in French research? In certain research areas, there will definitely be marking of time for another year. Perhaps M. Ortoli, the Minister of Industrial and Scientific Research, will be able in the days ahead to resolve some of the uncertainties undermining French research policy today.

ARCHITECTURAL ASSOCIATION

Still Alive

THE Architectural Association's School is now "active and healthy and well" in spite of the traumas of the past eighteen months, according to Professor Alvin Boyarsky, the newly appointed chairman of the school and its academic board.

The recent history of the school has been far from healthy. In February last year, plans for a merger with Imperial College, precipitated by the school's financial difficulties, fell through after six years of negotiation (see *Nature*, **225**, 575; 1971). Other proposed mergers went the same way and the school was left with the old problems and a lease that expires in 1976 and is unlikely to be renewed on the present favourable terms. There were fears that the school would have to be run down and closed. In spite of the problems, however, the AA's members and students at the school were determined to keep the school open and approaches were made to the Department of Education and Science (DES) and to local education authorities (LEAs) resulting in a rise in the fees from £460 to £580 and a fresh intake of 57 students this October.

Along with the new lease of life has come a reorganization of the school's structure. The post of principal, previously held by Mr John Lloyd, has disappeared and Professor Boyarsky is now responsible to a nine-man forum elected by the students, staff, association council and the membership.

Professor Boyarsky, a former staff member, is enthusiastic about the school's potential. Having departed in 1965 before the troubles began in earnest, he is far more concerned about future plans than past battles. He confesses to being "stunned" by the amount of activity in the school, sees its problems merely as "a challenge", plans to expand the school's evening work to involve more outside people and hopes to enlarge the school's already considerable international role.

But if things are brighter than they were, the clouds are still on the horizon. The school's fees of £580, paid by local education authorities, are much higher than the £60 to £75 paid to send students to other colleges and universities. In real terms, however, the school claims that the total cost of sending a student to the school is half to two thirds of that of sending him elsewhere—unlike other institutions, the AA is independent of central government finance. Although the Department of Education and Science has agreed to the steep increase of fees, it is insisting that there must be a viable plan for the future before the 1972 intake will be supported. What Mr John Smith, president of the Architectural Association, wants to see is a partnership between school and state, but he also feels that "to maintain our purpose we think it is important that we remain independent". Professor Boyarsky says that the biggest problem is not in finding the lump sum to renew the lease or find new premises (an appeal is to be run during the next year to help raise the money for this) but in finding the money for day to day expenses. He points out that an annual grant of £250,000 would solve the AA's problems by bringing the fees for the 485 students down to the same level as for other colleges and "to keep this cloud over this vibrant situation for so long for such a small sum of money is outrageous".

But whatever solutions are tried to remove the problems of running costs, further plans for mergers are not among them. The AA has come to value the very independence which causes its problems and even what sometimes seems to be this school's function as a "rogue elephant".

MUSEUMS

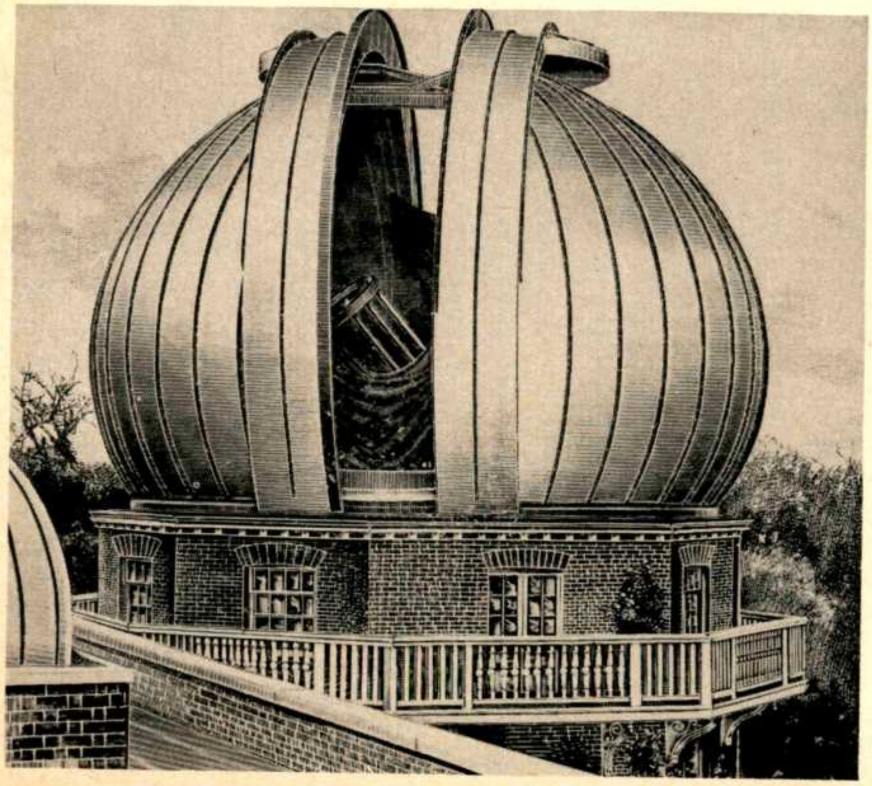
Telescope Transported

from a Correspondent

THE 28-inch refracting telescope that was in use at the Royal Observatory at Herstmonceux until a few months ago is being moved this week to its original site in the old Royal Observatory buildings at Greenwich. The telescope will become part of the museum of astronomy that is being established at Greenwich, and by late 1973 it should be available again for use by amateur and professional astronomers.

Removal of the telescope from the dome at Herstmonceux—which is needed for a new wide-angle telescope —and transportation and re-erection at Greenwich is an awkward engineering job. As well as the 27-foot telescope tube, the plan calls for the transport to Greenwich of the 26-foot polar axis and two 24-foot cast iron piers. But the chief task will be the reconstruction of the onion dome in which the telescope used to be housed while it was at Greenwich. The reconstructed dome will be built during 1972 and 1973, well in time for the celebrations in 1975 marking the tercentenary of the founding of the Royal Observatory. In the meantime the telescope and its mounting will be protected by a plastic drum which has already interrupted the familiar skyline of Greenwich.

The 28-inch telescope was built during the expansion of the observatory that occurred during the second half of the nineteenth century as a result of the appointment of the Cambridge mathematician George Airy as Astronomer Royal, although Airy retired before the telescope came into use, and he is not thought to have observed with it. Demand for the telescope arose through the so-called Neptune scandal: mathematicians in France and Cambridge independently predicted the existence of Neptune and the planet was observed by French astronomers, but there was no instrument in England capable of detecting it. As a result of the rumpus that this caused in scientific circles and in Parliament, the Admiralty—then responsible for the Royal Observatory—agreed to the commissioning of a 28-inch telescope to replace the 12.8-inch refractor, but insisted on economic grounds that the same mounting be used. But in order to accommodate the extra length of the new telescope, an onion-shaped dome had to be constructed—of *papier mâché* on an iron frame—that remained a feature of the Greenwich skyline until 1954.



National Maritime Museum

The original onion-shaped dome of the 28-inch refractor at the Royal Observatory, Greenwich.

RESEARCH ASSOCIATIONS

Where Next?

THE Sira Institute seems to be swimming against the economic tide. The annual report, now published, shows that income increased from £536,510 to £588,115 over the year just past in spite of a decrease in grant from the Department of Trade and Industry of £30,790 to £227,270. Dr Sydney Jones, chairman of Sira, is cheerful enough about this modest increase in business but it seems clear that the research associations will in future be much more keen to sell their services in the open market. No doubt a research association concerned with scientific instruments has more scope than most.

The position of research associations is still far from clear. Sira itself is in the second year of a five-year plan during which the government grant will be steadily decreased, and there is no guarantee of continued support thereafter. Dr Jones's optimism about the immediate future does not change the view that, in the long run, government aid in some form will be necessary if the research associations are to survive. Many of them, Sira included, are hoping to attract government money in the form of research and development contracts rather than continuing grants.

In the past year, Sira seems to have benefited a little from the way in which economic pressures have forced companies to take a more hard-headed view of research and development expenditure. There have been some occasions when companies have put research and development contracts with Sira instead of trying to do the work themselves.

Sira's income from general subscriptions last year was the same as during 1969–70 but it was achieved by smaller subscriptions from a larger number of companies, possibly reflecting this trend. Dr Jones added that the increase in Sira's income came from an 11 per cent increase in project contributions and a 27 per cent increase in contract income, together with a 5 per cent decrease in expenditure achieved by reducing the staff by over 14 per cent to its present level of 190 employees.

Two German companies, Jenaer Glaswerk Schott and Gen. of Mainz and Siemens AG, have joined and are cooperating on projects concerned respectively with the image control of fibre plates and ion selective electrodes for analysis and monitoring. Another sign of the times as far as research institutions are concerned is that Mr S. S. Carlisle, director of Sira, is a member of a committee of the Department of Trade and Industry that coordinates collaboration between the instrument making industry in Britain and that of Eastern Europe.

NEW WORLD

Rogers May Yet Win Cancer Stakes

by our Washington Correspondent

A UNANIMOUS vote in the House Subcommittee on Public Health and Environment last week may ensure that the National Institutes of Health is not broken up by Congressional efforts to help find a cure for cancer. The subcommittee has approved a bill designed to give the National Cancer Institute a total of $1,600 million over the next three years, but to keep it as an integral part of the NIH. The bill, which is in many important respects the same as that introduced in September by Paul G. Rogers, chairman of the public health subcommittee, and five of his colleagues (see *Nature*, **233**, 228; 1971), is also believed to be acceptable to the White House—a factor which could greatly ease its passage through the rest of the Congressional mill.

Mr Paul G. Rogers: "I anticipate no fight."

Before Mr Rogers introduced his bill in September, it seemed that the House would follow closely the footsteps of the Senate and agree to a cancer cure programme administered by an agency which, to all intents and purposes, would be independent of the NIH. But there is now a very good chance that Mr Rogers's bill will prevail over the Senate version, and that the vastly expanded cancer research programme will be administered by the NIH. Last week's important vote in the subcommittee sends the bill to the full committee from which, if approved, it will be reported to the House. The House is expected to vote on the bill early in November.

Even if the House passes the bill in its present form, however, some of the most crucial decisions on the future organization of cancer research would still have to be taken, for at that stage the differences between the House and Senate versions of the cancer cure bill would have to be reconciled. If the House version is unacceptable to the Senate, the whole issue would have to be decided behind the closed doors of a conference committee composed of representatives of both legislative chambers, and it is at this stage that the Rogers bill is now most likely to be emasculated. Mr Rogers said last week, however, that he expects no "committee, floor or conference committee fight".

Mr Rogers bases his optimism on several important factors, chief among which is that the bill is unlikely to provoke spirited opposition from either the White House or from the lobbyists who successfully inveigled the Senate into passing a bill designed to set up an independent cancer cure agency. Rogers took the far-sighted precaution of having representatives from the White House and from the Department of Health, Education and Welfare participate in the committee's deliberations when it marked up the final version of the bill, and he believes the Administration to be favourable to its objectives. One of the most influential lobbyists for the Senate version said last week that he believes "we have got a good bill". The fact that the bill was approved unanimously by the subcommittee may also ensure that it is not substantially altered by the full committee, whose chairman, Harley O. Staggers, introduced the Senate version of the bill into the House, but who declared at the opening of hearings in the subcommittee that he had not then formed any set convictions on the optimum organization for cancer research.

Mr Rogers's committee has held four full weeks of hearings on the bill, during which a string of witnesses from the biomedical community testified against the idea of setting up an independent agency. Although few new arguments emerged during the hearings, the subcommittee was evidently impressed by the fact that apart from the American Cancer Society, no major scientific organization supported the main points of the Senate passed version of the bill.

The members of the subcommittee were, nevertheless, under great pressure from skilful lobbyists, and Rogers said last week that the bill had been approved by his committee "in spite of the pressures that have been mounted". Only two days before the subcommittee approved the bill, for example, the American Cancer Society and a group calling itself the Citizens Committee for the Conquest of Cancer found it necessary to take full page advertising space in twenty-four newspapers (including papers in each of the ten congressional districts of the members of the subcommittee) to explain the virtues of the Senate version—an enterprise which drew from one member of the subcommittee the remark that the money could have been put to better use in cancer research.

As a result chiefly of the intensive lobbying, and in part of testimony received during the hearings, the original bill submitted by Rogers and his colleagues underwent some surgery. No vital parts were removed, but a few extra items were grafted on by the subcommittee.

The bill would give the National Cancer Institute a budget of $400 million for the 1972 financial year (which started on July 1)—an increase of more than $60 million over the amount appropriated by Congress last month and some $170 million more than the institute received last year—rising to $500 million next year and $600 million in 1974. The NCI's budget would be drawn up by the institute's director (who would be promoted to the rank of associate director of the NIH), and transmitted directly to the President. The director of NIH, the secretary of HEW and the Advisory Cancer Council would be able to comment on but not alter the budget.

Those provisions were part of the original bill introduced by Rogers, and survived intact the subcommittee scrutiny. But the bill reported out of the subcommittee also contains four important additions to the original bill, none of which, however, alters the philosophy that underlies its chief intentions.

First, the new bill would create 15 clinical research centres which could each receive block grants of up to $5 million a year from the NCI, and this grant arrangement is also extended to other existing cancer research centres, such as the Sloan-Kettering Institute in New York.

The idea behind the proposal is that individual institutions would be given greater flexibility in their research arrangements since they would not have to come to the NCI with thirty or forty applications for grants for specific projects.

Another proposal designed to speed up grant applications is a provision in the bill which would allow applications for grants of $35,000 or less to be studied by peer groups and approved by the director of the NCI without first being studied by the National Cancer Advisory Council.

The original bill had offered this proposal only for grant applications involving $20,000 or less, and the idea is to cut out a bottleneck which arises because the National Cancer Advisory Council meets only three times a year. The proposal would lift 40 per cent of the grant applications from its shoulders, and greatly increase the time available for the council to plan overall strategies for cancer research without being bogged down with what amounts to formal decisions.

The new bill also specifies a committee of three as a liaison between the President and the director of the National Cancer Institute. The suggestion for this committee is reported to have come from Mr Ancher Nelsen, ranking Republican on the Rogers subcommittee, as a means for helping the President to exercise his control over the programme by offering scientific reports and advice (two of the three members of the committee would be practising scientists or physicians).

Also included in the new provisions is a call for reactivation of federally funded cancer control programmes (pap tests, oral and breast examinations and so on) that were phased out by the Office of Management and Budget last year. The bill asks for $20 million this year, rising to $40 million in 1974 for this purpose.

If Rogers does manage to steer his bill through the rest of the Congressional mill, he will have achieved the distinction of defeating proposals put forward both by Senator Edward M. Kennedy and by the Administration. Kennedy introduced a bill earlier this year which called for an independent cancer research agency, on the lines suggested by a panel of cancer researchers and businessmen (see *Nature*, **228**, 1133; 1970).

The Administration, anxious to prevent the NIH from being broken up by the proposal, introduced a bill designed to keep the cancer effort within a National Cancer Institute elevated to the position of a bureau within NIH, but later entered into a compromise with Kennedy which in effect put the Administration's name on Kennedy's original proposals. That "compromise" went through the Senate with only Senator Gaylord Nelson of Wisconsin registering his dissent. Nelson's opposition to the Senate bill as much as Rogers's tenacity in spite of intense pressure has helped to steer the congressional debate back on realistic lines.

HEREDITARY DISEASE

Congress Against Sickle Cell

by our Washington Correspondent

ALTHOUGH Congress may be close to deciding how to spend several hundred million dollars a year on cancer research (see page 516) it stands little chance of running out of diseases to conquer. The latest object of potential Congressional largesse is sickle cell anaemia, which afflicts about one in every five hundred blacks, killing up to half its victims before they reach twenty. Identical bills introduced into the Senate and the House of Representatives last week call for a total of $90 million to be spent over the next three years on genetic counselling, screening, public education, research and treatment for sickle cell anaemia. Apart from the £1,600 million being requested for cancer research, the sum being asked for sickle cell anaemia may seem paltry, but compared with the $1.2 million budgeted last year for research and treatment of the disease, it is a huge increase.

Introduced into the Senate by John V. Tunney of California, and into the House by Walter Fauntroy, the District of Columbia delegate, the bills have attracted an impressive list of cosponsors including Edward M. Kennedy and several members of his Senate health subcommittee. One bill calls for a national programme aimed at the prevention of sickle cell anaemia, while the other seeks to institute a pilot programme in the District of Columbia, which has a larger percentage of black people than any other city in the United States. The chief aim of the programmes outlined in the bills is greatly to increase federal funding for screening and genetic counselling.

The National Sickle Cell Anemia Prevention Act, as it is labelled, would make available $25 million a year for grants to public and non-profit-making enterprises for the establishment and operation of screening and counselling programmes, and a further $5 million a year for research into the treatment and diagnosis of the disease. When he introduced the bill into the Senate last week, Senator Tunney said that "compared with other serious diseases, sickle cell anaemia has received only minimal attention and research". Citing the fact that diseases such as phenylketonuria and cystic fibrosis, which predominantly affect whites, consistently attract large slices of research money, while there is not even a national volunteer organization to raise money for sickle cell anaemia, Tunney called for a vastly expanded effort to make up for the neglect.

Similar sentiments were expressed by President Nixon in February, when, in his health message to Congress, he labelled sickle cell anaemia a targeted disease for concentrated research. "It is a sad and shameful fact that the causes of this disease have been largely neglected throughout our history," he said. "We cannot rewrite this record of neglect, but we can reverse it." With those words, he requested a 500 per cent increase in the budget for research and treatment of sickle cell disease, to a new total of $6 million.

Welcome as this new emphasis on sickle cell anaemia is, simply counting dollars devoted to sickle cell research can offer a misleading impression, for, as many workers are quick to point out, basic research on haemoglobin is often directly applicable to sickle cell research. One scientist engaged on haemoglobin research said last week, for example, that "there is no disease about which we have more sophisticated knowledge".

National programmes for counselling and screening have, however, not kept pace with research into the underlying causes of the disease. It is estimated that about seven per cent of the American black population carry one defective gene, and that one in every five hundred children born of black parents will receive a defective gene from each parent and develop sickle cell anaemia. The disease could, of course, be prevented if partners who both carry the sickle cell trait avoid having children, which requires an effective screening and counselling programme.

As with all such programmes, however, there is the problem of advising partners against having children, when there is only a one in four chance of their offspring developing the disease. Nevertheless, a national programme aimed at providing education and proper guidance on sickle cell anaemia will be a great improvement on the present situation in which the first many people hear about the disease is when one of their children develops it.

Dr C. Lockhard Conley, professor of medicine at Johns Hopkins Hospital in Baltimore and a specialist in haematology, said last week that he believes $25 million a year could be well spent on sickle cell anaemia. Pointing out that the money appropriated recently by Congress for research on sickle cell anaemia would provide each patient with only about $250—enough for about two days in hospital—and that there have been several recent advances in treatment of the sickle cell crisis, Dr

Conley said, "If I had to select a genetic disease for which there is a real and well founded hope of progress, it would be sickle cell anaemia".

President Nixon also used the opportunity to give publicity to his $100 million dollar request for additional funds for cancer research, and to the Administration's cancer cure programme, which was passed by the Senate in July. "I again urge the House of Representatives to act promptly on this matter so we can get on with this important work," he said.

CANCER RESEARCH

Fort Detrick Lives Again

by our Washington Correspondent

A NEAT solution of the twin problems of what to do with a redundant laboratory and of how to spend the vastly increased budget for cancer research was provided this week when President Nixon announced that the former biological warfare research station at Fort Detrick would be turned over to the National Cancer Institute for cancer research. The complex of nine laboratories at the Maryland research station were once the most sophisticated facilities for research on bacteriological weapons in the United States. But all that was stopped in 1969, and the future of Fort Detrick has since been in the balance.

Last year, the Senate voted to give the National Institutes of Health the $15 million needed to convert Fort Detrick's laboratories from bacteriological warfare research to a variety of biomedical research problems. It was then believed that the laboratories would be used chiefly by the National Institute of Allergy and Infectious Diseases and by the National Cancer Institute, for research on hazardous viruses and on suspected tumour viruses. The special facilities at Fort Detrick, which include negative pressure rooms to prevent escape of dangerous organisms and excellent culture and storage facilities, are expensive and ideal for virus research of all kinds.

The Senate's decision, the result of an amendment introduced by Senator Charles Mathias of Maryland, was, however, reversed by a conference committee which asked that the proposals should be further studied by the Department of Health, Education and Welfare. In the meantime, the research station's complement of microbiologists, whose future had been uncertain since the decision to renounce offensive bacteriological weapons was taken in 1969, began to leave the station in droves.

The decision to beat a sword into a ploughshare by transferring Fort Detrick from warfare research to study the problems of cancer was announced last Monday when President Nixon visited the establishment. Pointing out that the transfer would "help advance important public goals even as we alleviate the economic burdens which threaten idle workers and their families", Nixon said that he hopes the conversion would be completed by early 1972. The research station may provide work for up to 700 cancer researchers.

Short Notes

Justification for NASA

A RECENT address by Dr James C. Fletcher, Administrator of NASA, brought out the following juggling of figures to justify NASA's budget: "Let us put NASA's budget figure in perspective along with the rest of the federal budget. $3,300 million is actually less than one and a half cents of the federal budget dollar. We are already spending 42 cents of the federal budget dollar on human resources, including health, income, security and veterans benefits. And we are also spending 34 cents of the federal budget dollar on national defence. So even if the space programme were abolished entirely—which would be a calamity for this country—the amount available for other programmes, one and a half cents, would be relatively insignificant.

"Looking at it another way, $3,300 million is less than one third of one per cent of the gross national product and it is only 16 dollars for each person in this country." Looking at it another way, $3,300 million is $700 million more than Congress appropriated for housing and urban development.

Cannikin

CRITICS of the AEC's plan to explode a five megaton nuclear weapon under Amchitka Island this month were disappointed in their expectation that President Nixon would announce cancellation, or at least postponement, of the test, when he met Emperor Hirohito of Japan recently. The White House is in fact now saying that President Nixon may not have any intention of calling the test off, that an announcement to go ahead can be expected soon now that Mr Kosygin's visit to Canada is over. The test is designed to monitor the X-ray output of the warhead of the Spartan anti-ballistic missile that forms the long-range component of the Safeguard ABM system.

NASA

DATA gathered by the Earth Resources Technology Satellite (ERTS-A) and the Earth Resources Experiment Package (EREP) carried on Skylab will be used to provide information on such diverse topics as vegetation damage from highway construction in Maine to the movement of sediment in San Francisco. ERTS-A will be launched in spring 1972, and Skylab is scheduled for launch early in 1973. These Earth monitoring and data gathering satellites have drawn the greatest number of proposals ever received by NASA for any scientific satellite—700 had been submitted by June this year, of which some 430 have initially been selected.

The satellites, which are intended primarily to study the feasibility of remote sensoring from satellites of natural resources, will provide multispectral images of the Earth's surface. Similar techniques were also employed aboard a high-flying aircraft recently used with some success in an experiment conducted jointly by NASA and the Department of Agriculture designed to gather information on southern corn leaf blight in the United States. The aircraft surveyed 72,000 square kilometres of cornlands between June and September with infrared photography.

Methotrexate

THE Food and Drug Administration has decided to allow the controversial drug methotrexate to be used for severe cases of psoriasis, a debilitating skin disease. The latest issue of the *FDA Bulletin* includes an outline of the cases in which the drug should be used: they include only those cases of psoriasis that have proved to be resistant to conventional treatment, and the drug should be dispensed to patients only by the physician.

This announcement follows three days of hearings on the FDA's handling of methotrexate by the House Intergovernmental Relations Subcommittee, after which Benjamin S. Rosenthal, a vocal critic of FDA policies, and Mr L. Fountain, chairman of the subcommittee, accused the FDA of extreme negligence in taking no action to stop physicians from illicitly prescribing the drug. Mr Fountain warned the FDA that since there had been 71 adverse reactions to methotrexate reported during the eight years that it had been on trial, the drug ought not to be licensed for use against psoriasis.

NEWS AND VIEWS

Time Lost in Air Travel

No airline has yet used the argument, in its advertising, that ageing is less in high-speed travel because of the relativistic time-dilatation phenomenon. Travel agents should therefore know that J. Hafele of Washington University and R. Keating of the Naval Observatory, Washington, have taken a pair of atomic clocks on a round-the-world air trip to show that this minute effect is indeed measurable (in clocks, if not in people). Time dilatation is, of course, a familiar feature in experimentation, but such a direct test, if intended to settle the "clock paradox" controversy, is something rather different. Followers of this controversy will know that one school has always maintained that a direct test is essential to decide the issue; another school would accept the argument of W. Cochran (*Nature*, **179**, 977; 1957) that π^+ meson experiments, like one performed by R. Durbin and colleagues of Columbia University using the Nevis cyclotron, are equivalent. It is understood that Hafele and Keating used Hewlett-Packard caesium beam atomic clocks, which would presumably be acceptable to everybody.

Relativistic effects at aircraft speeds are mostly well beyond the limit of measurement. If acceleration is negligible, a clock travelling with speed kc (c=speed of light) is slowed by a factor $f=\sqrt{(1-k^2)}\sim 1-\frac{1}{2}k^2$ for small k, when observations are made by a "rest" observer. If the speed of transport is 600 m.p.h., f is about $1-(4\times 10^{-13})$, so that an accuracy of one or two parts in 10^{13} is needed for an experimental test. This is just about the limit of the caesium clock's ability under reasonable conditions. The total time "saved" over a 36-hour trip at the same speed is roughly 5×10^{-8} s.

The next problem that faces experimenters using transported clocks is that of acceleration. An "ideal" clock in relativity theory is one which is not directly affected by acceleration, or more precisely, one for which the clock hypothesis is valid. The clock hypothesis is that the slowing-down factor f still has the value $\sqrt{(1-k^2)}$ at each instant, even when the speed ratio k is variable. It is difficult to establish theoretically whether any but the simplest types of clock obey this hypothesis because the behaviour of the governing mechanism, especially in its rigidity, would need detailed analysis. The easiest way for the experimenter to overcome the problem is to ensure in some way that acceleration effects are kept within known bounds, of a smaller order of magnitude than that of the effect sought. Fortunately, this is possible for the caesium clocks in question, because experience has already been gained in transporting similar clocks by land and air (for example, in Europe). After short journeys, where time dilatation will not have been significant, it has been found that normal handling, take off and landing accelerations, and modest turbulence in flight do not introduce discrepancies in total travel time as recorded by these and laboratory based clocks.

Temperature and pressure variations during their flight should likewise have posed no very great problems for Hafele and Keating. On the other hand, the clocks are sensitive to magnetic field: because each is inherently dependent on the existence of a steady magnetic field, care has to be taken that one does not affect the other when two are placed close together. It is naturally supposed that adequate screening will have been possible.

Finally, there is the most important "extraneous" effect, which, being relativistic in character, must raise doubts as to the validity of the whole experiment or, at very least, as to its importance. This concerns the gravitational "blueshift" predicted by general relativity or, more simply, by the principle of equivalence. Einstein's principle of equivalence asserts that any gravitational field is locally indistinguishable from an equivalent acceleration of the reference system, and so the behaviour of a clock at rest in a permanent gravitational field can be determined by treating it as though it were instead being accelerated in gravitation-free space. Identical clocks, A and B, fixed on a rigid rod which accelerates uniformly in the direction AB do not keep in synchronization; B is observed to run fast, at A, because periodic light signals from B to A are received at an increased rate owing to Doppler shift. The shift arises because A's speed increases during the time the signals are travelling. Therefore, in the equivalent situation of clocks at rest at points with different gravitational potentials, the one (B) at higher potential gains over the other (A) at lower potential. For modest field variations and a small separation of clocks, the ratio of rates is $F=1+U/c^2$, where U is the difference in potential at A and B. Near the Earth's surface, $F=1+gh/c^2$, for clocks vertically separated by a height h. R. V. Pound and G. A. Rebka, jun., of the Lyman Laboratory at Harvard University verified this formula in 1960 using the Mössbauer effect.

When B is an airborne clock and A is at rest on the ground, the combined effects of time dilatation and gravitational blueshift results in a rate ratio fF for $B:A$ (observed from the ground). Taking the flight speed to be 600 m.p.h. the two effects cancel ($fF=1$) when $F\sim 1+(4\times 10^{-8})$, corresponding to a modest flying height of 2¼ miles. If the aircraft flies at a height of 6 miles, the gravitational effect is more than twice as great as the opposing one of time dilatation, and the airborne clock gains about 5×10^{-8} s during a 36-hour trip. It would be easier to separate the two phenomena using an artificial Earth satellite in place of an aircraft, as has been proposed in the past.

In places such as Denver, Colorado (at a height of 1.6 km), it is becoming common in high-precision timekeeping to apply a correction for gravitational potential. This procedure is unexceptional when relativistic time effects are not in dispute. But because similar large-order corrections will have to be applied to the experimental data of Hafele and Keating, their experiment cannot be expected to silence dissidents in the clock paradox controversy. Because time dilatation itself is so commonplace it is hard to see what other purpose the experiment has. No doubt the published account will eventually tell us.

A New Theory of Muscle Contraction

One of the outstanding mysteries of molecular biology is the mechanism whereby chemical energy is converted into work during muscular contraction. In spite of significant advances in the past few years in knowledge of the details of muscle structure and of the biochemical reactions involved in contraction, no comprehensive theory has yet been proposed which satisfactorily explains the molecular events involved in this process. A major difficulty lies in the complete ignorance of the nature of the basic mechanism involved. Mechanisms which have been proposed range from mechano-chemical processes, as suggested by Davies (*Nature*, **199**, 1068; 1963), to the electrostatic mechanisms proposed by Elliott, Rome and Spencer (*Nature*, **226**, 417; 1970).

Experiments on muscle contraction tend to fall into one of three distinct categories—structural, biochemical or physiological—and these apply also to contraction theories, which may explain observations from one area, but frequently give only a superficial consideration to observations from the other areas. Because results obtained in one category normally complement results obtained in the other two, a complete explanation of the contraction process can only come when results from all areas are melded into a single theory. Data from structural studies can provide the framework in which biochemical processes producing the energy conversion can take place. It is physiological data, however, which can test the relevance of any structural or biochemical theory to living muscle and its normal behaviour.

On page 533 of this issue of *Nature*, A. F. Huxley and R. M. Simmons propose a theory of contraction which combines observations from two of the three categories—structural and physiological. Their theory has evolved from A. F. Huxley's theory (*Progr. Biophys.*, **7**, 255; 1957) which has been reworked to take account of recent structural and physiological observations.

Huxley's original theory followed the discovery in 1954 of the sliding filament mechanism for muscle contraction. Huxley suggested that contraction resulted from the formation of actin–myosin links with specific elastic properties between the two types of filaments. The rates of making and breaking the links governed the extent and speed of the muscle's contraction. Calculations based on this theory could account for several known physiological relationships in muscle. Details of the structural components and of the biochemical reactions could not, however, be specified.

Recent experiments by Huxley and Simmons on transient tension effects in single fibres of frog muscle after quick stretches or releases have enabled them to specify certain properties of the actin–myosin links. Although Huxley and Simmons state that their general proposals can be applied to several structural models and are similar to a much earlier theory of visco-elastic behaviour of high molecular weight polymers proposed by Eyring (*J. Chem Phys.*, **4**, 283; 1936), they have based their theory on H. E. Huxley's recent structural model (*Science*, **164**, 1356; 1969).

In H. E. Huxley's model, myosin and actin filaments slide past one another (and thus cause shortening) through the formation of "cross-bridges" between the two types of filaments. Each cross-bridge results from the attachment of a projecting part of the thick myosin filament (myosin "heads", equivalent to heavy meromyosin subfragment one) to specific sites on the thinner actin filaments. Shortening at each site is produced by a change in the angle that the cross-bridge makes with the filament axis so that the actin filament is pulled relative to the myosin filament. Individual cross-bridges are formed cyclically to produce a smooth shortening motion. The head of the myosin molecule is able to bridge the variable gap between the filaments by swinging out from a hinged region part way along the straight and otherwise rigid shaft of the molecule. A cross-bridge is formed when the myosin head attaches to an actin filament. The part of the myosin molecule which hinges outward corresponds to heavy meromyosin subfragment two.

The experiments of A. F. Huxley and Simmons suggest the existence of two elastic elements in series which they identify with the cross-bridge structure. A stiff, undamped elasticity is assigned to the straight, hinged part of the myosin molecule (subfragment two), and a damped elasticity, with a time constant of a millisecond or less, to the myosin head–actin complex. During contraction each myosin head–actin attachment shifts through a series of stable positions (probably three), each with a lower potential energy than the last. The motion so produced, when coupled with the elasticity of the straight connecting link, can give a smoothly-changing force between the filaments. The authors have observed in experiments that a rapid change of length in the muscle fibre is associated first with a rapid tension change which parallels the length change (an undamped elasticity) and then with a (damped) recovery to a tension intermediate to the initial tension and that at the end of the length change. The tension at the end of a length change, that after the rapid recovery, and the rate of tension recovery were measured as a function of the length change imposed. The curves obtained were fitted closely by curves calculated from the theory.

To this extent, then, the theory agrees well with experimental observation. Huxley and Simmons imply, but do not demonstrate here, that their theory can also account for such established physiological data as force-velocity curves and heat production. This aspect will doubtless be covered in a fuller treatment promised for the future. The theory should also be checked quantitatively against such other observations as the length transients appearing after rapid tension changes measured by Podolsky and his colleagues (see *Proc. US Nat. Acad. Sci.*, **64**, 504; 1969). Equally important, is the theory compatible with the biochemical knowledge of muscle contraction—the energy requirements during contraction, and the roles of adenosine triphosphate, phosphocreatine and calcium?

The success of any theory ultimately resides in the future experiments it stimulates. If the Huxley and Simmons theory enables physiologists and others to develop meaningful experiments to test its predictions against existing structural and biochemical knowledge, it will have done valuable service to muscle research, whatever its fate in the archives of contraction theories.

GLYCINE

In Nerve Terminals

from our Neurochemistry Correspondent

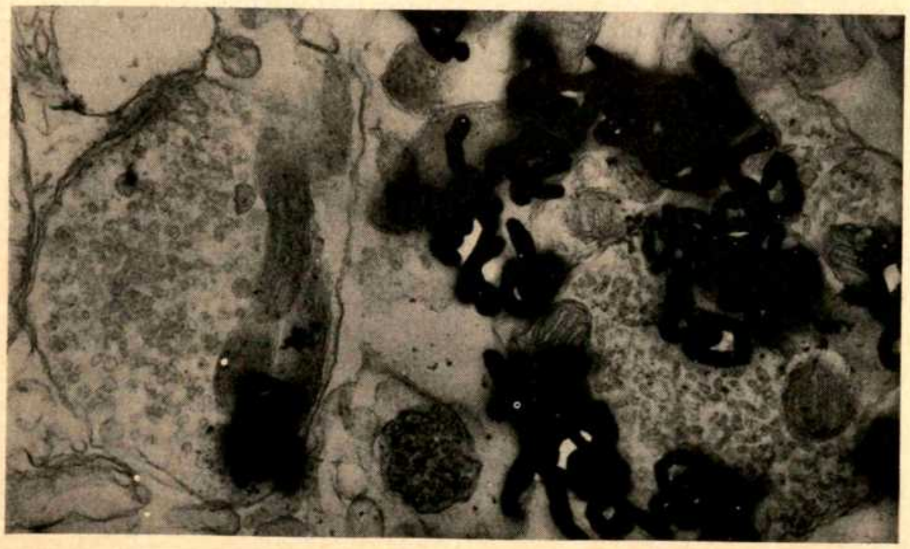
By one of those strange coincidences which occasionally arise in the world of scientific research, the current issue of *Brain Research* contains reports of two studies carried out independently by T. Hökfelt and Å. Ljungdahl at the Karolinska Institute, Stockholm, and by A. I. Matus and M. E. Dennison at University College, London, who have demonstrated by autoradiography that tritiated glycine, after incubation with slices of rat spinal cord, becomes associated predominantly with nerve terminals (*Brain Res.*, **32**, 189 and 195 ; 1971).

Glycine, apart from its universal role as an essential component of proteins, is believed to serve an additional function in the spinal cord as a mediator of transmission at inhibitory synapses. Inhibition in the nervous system plays a crucial part in the regulation of neuronal activity ; in the spinal cord, for instance, the motoneurones of the ventral horn, which give rise to axons transmitting information to skeletal muscles, are subject to a variety of inhibitory influences. Evidence implicating glycine as a spinal inhibitory transmitter (reviewed by Hebb in *Ann. Rev. Physiol.*, **32**, 165 ; 1970) arose from electrophysiological studies showing that iontophoretic application of glycine to certain cells in the cord causes an increase in the membrane potential of those cells similar to that occurring during natural inhibition. This hyperpolarization is blocked by the convulsant alkaloid, strychnine, which also blocks certain spinal inhibitory pathways. Furthermore, the distribution of endogenous glycine in the spinal cord suggests that it is concentrated to an extent greater than would be required for a general "metabolic" function in areas where inhibitory neurones may be present.

If glycine is a neurotransmitter, a mechanism should also exist for its rapid removal from extracellular sites after it has exerted its physiological effects. Transmitter inactivation may be achieved by enzymatic destruction, by uptake into adjacent cells or nerve endings, or simply by diffusion from the site of action. It has been demonstrated that slices of rat spinal cord can accumulate exogenous radioactively-labelled glycine from an incubation medium by a high-affinity active transport process, but until recently there was little evidence as to the precise cellular sites responsible for this uptake. In the cerebral cortex, where γ-aminobutyric acid (GABA) is believed to be the principal inhibitory transmitter, there is an analogous uptake system and subcellular fractionation studies have shown that a proportion of the labelled amino-acid taken up into slices may be recovered in a fraction containing nerve endings. Moreover, Bloom and Iversen (*Nature*, **229**, 628 ; 1970) were recently able to demonstrate by electron microscope autoradiography of cortex slices or homogenates after incubation with ^{3}H-GABA that the label becomes localized over certain nerve terminals and preterminal axons. The present studies, by Hökfelt and Ljungdahl and Matus and Dennison, were an attempt to localize similarly the sites of uptake of ^{3}H-glycine in slices of spinal cord using autoradiography at both the light and electron microscope levels.

The results from both groups are strikingly similar. Light autoradiograms showed a higher concentration of grains over grey than white matter, and, at the ultrastructural level, heavy accumulations of grains were seen over certain terminals, whereas others showed no activity. Matus and Dennison suggest that those terminals which were heavily labelled are those containing "flat" as opposed to round vesicles (see figure), although this possibility is not discussed by Hökfelt and Ljungdahl. This suggestion is, however, of considerable interest in view of the hypothesis of Uchizono (*Nature*, **207**, 642 ; 1965) that the shape of vesicles present in terminals may be correlated with the physiological role of those terminals—excitatory endings containing round vesicles and inhibitory endings with flattened ones.

Previous studies have shown that of the labelled glycine taken up by spinal cord slices, only 2 per cent is incorporated into protein, the remainder being recoverable as free glycine. It has also proved possible to demonstrate the release of labelled glycine from previously loaded tissue slices by electrical stimulation (J. M. Hopkin and M. J. Neal, *Brit. J. Pharmacol.*, **40**, 136 ; 1970). This suggests that exogenous glycine may enter the same sites as are occupied by the endogenous transmitter, and the present results may thus be interpreted as evidence that glycine is present in certain inhibitory nerve terminals of the spinal cord, thus adding considerable weight to the hypothesis that glycine is a spinal inhibitory transmitter.



Electron microscope autoradiograph of a selected area from the ventral horn of rat spinal cord, after incubation in tritiated glycine, showing heavy accumulation of grains over a "flat" vesicle synapse on the right as compared with one containing round vesicles on the left. ×27,200. (From *Brain Res.*, **32**, 195 ; 1971.)

TROPICAL ECOLOGY

Man-made Changes

from a Correspondent

Three areas of concern were highlighted at the meeting of the Tropical Ecology Group of the British Ecological Society at University College, London, on October 4: first, the deterioration in the resources for cattle ranging following successful animal health control measures in Africa; second, the replacement of polyspecific forest and grassland by forest monocultures; and, third, the effects of tourism on tropical islands. The medical implications of large-scale irrigation for rice development in Kenya were also considered.

Contributions on cattle ranching in tsetse-fly infested savanna in Tanzania, by Mr J. Ford (University of Oxford), and on the effects of animal health control measures against rinderpest, by Mr A. Blair Rains (Land Resources Division, Overseas Development Administration), both illustrated very clearly, and with dramatic photographs, that increases in cattle numbers are followed by encroachment of shrubs, such as *Acacia* species, into grassland areas. Mr Ford's examples came from a large-scale attempt to ranch cattle, using drug prophylaxis against trypanosomiasis, started in eastern Tanzania in 1954; meat production increased for about ten years, then declined as range conditions deteriorated. Mr Blair Rains's examples came from Botswana and the Gambia, where control against rinderpest and other bovine diseases has been startlingly successful. Although cattle marketing is developing, large herds are still kept for traditional purposes, water supplies are no longer limiting, and inability to control stocking levels has resulted in either shrub encroachment or in the nearly complete destruction of vegetation over very large areas around water points.

Dr D. C. Dawkins (Commonwealth Forestry Institute, Oxford) spoke on the effects of forest management, with operations which range in scale from merely weeding out hollow trees, resulting in the loss of holes for tree dwelling fauna, to total clearing and replacement by forest monocultures, often of exotic species. His colleague Mr P. J. Wood then discussed ecological anxieties arising from these monocultures which are now replacing forest and grassland in many tropical lands; in the East African Highlands alone some 15,000 hectares of conifers are being planted each year. The long-term effects of these monocultures have to date been little studied, but the evidence available suggests that the resulting erosion and alteration of soil profiles present greater dangers than the introductions of pests and pathogens, or than changes in water balance or soil microflora. The "ecological spillover" effects are most in need of study. The ensuing discussion brought out the problems of ensuring that areas of indigenous forest are preserved for conservation purposes in countries which are now independent.

The unprecedented pressures of affluence and cheap travel on the limited tropical littoral resources of West Indian islands were treated in stimulating and well illustrated contributions by Mr M. A. Brunt (Land Resources Division, Overseas Development Administration) and by Dr M. E. C. Giglioli (Mosquito Research and Control Unit, Cayman Islands). In Jamaica, the replacement of mangrove swamps by man-made beaches has provided suitable breeding places for biting sand flies (*Culicoides*), with the result that there have been local infestations of these insects. In the Cayman Islands, mangrove swamps have been flooded to control the biting mosquito *Aëdes taeniorhynchus*, and cleared and filled with marl for housing development. The cleared areas have remained bare of vegetation, leaving the land exposed to damage from hurricanes which frequent this area. Dr Giglioli described aerial spraying operations, and stressed the importance of inviting local people to share in control operations to ensure the acceptance of the necessary measures by the local community.

OCEANIC RIDGES

Problems with Chemistry

from our Geomagnetism Correspondent

THE general hypothesis of seafloor spreading envisages the upwelling of peridotitic mantle material beneath mid-oceanic ridges which are known to be regions of relatively high heat flow. Partial melting of the material then takes place producing basaltic liquids which are injected into comparatively narrow regions near the ridge axis. The existence of high thermal régimes beneath ridge axes implies that beneath ridges the silicate melts are generated at shallower depths, and thus lower pressures, than would normally be the case. Because the compositions of liquids arising from partial melting of mantle material are strongly dependent upon the pressure under which such liquids are produced, the prediction is then made that the compositions of basalts injected at ridge axes should be significantly different from that of volcanic rocks produced well away from ridges. In particular, if the simple theory is valid, ridge basalts should tend to be tholeiitic whereas non-ridge basalts would be expected to be more alkaline.

But these cherished assumptions have taken a sharp knock with the publication by Bonatti and Fisher (*Earth Planet. Sci. Lett.*, **11**, 307; 1971) of compositional data for basalts from the East Pacific Rise and other Pacific sites removed from the rise. Most of the rise rocks in question were from a basalt pavement which outcrops along the axis of the rise between 14° S and 6° S though two others were obtained from 18° S and near to the equator, respectively. All were less than one million years old according to radiometric or fission track dating. The non-rise samples were collected from five seamounts lying between 450 and 1,500 km from the rise axis and all were less than five million years old, again according to radiometric or fission track dating. It is possible, of course, that the seamount samples were emplaced at the rise axis and subsequently spread away to their present positions and if this were so—and assuming a reasonable spreading rate of 4 cm a year—their ages would lie in the approximate range 11–35 million years. The measured ages rule this out, however, and suggest that, on the contrary, the seamounts were formed more or less in their present positions. The contrast between rise and non-rise basalts is thus valid.

The surprise comes from comparisons of normative compositions and the degree of silica saturation for the rise and non-rise basalts. When normative compositions are plotted on the Q-Di-

Similarities between Pulsar Models

THE two widely favoured rotating neutron star models for pulsars differ less widely than is sometimes believed, according to an article by L. Mestel, of the University of Manchester, in next Monday's *Nature Physical Science*. These two models are the axisymmetric model of Goldreich and Julian (the "non-oblique rotator") and the oblique rotator of Pacini and Ostriker and Gunn.

Goldreich and Julian found that for their model, with its relatively dense magnetosphere, the vacuum electric field ($\mathbf{D} = \varepsilon_0 \mathbf{E}$) just outside the surface of the star has a component along the magnetic field which produces electrical forces on the charges in the surface layer which are much greater than the gravitational forces. This results in a motion of electrons out of the star, so that the steady state of the model includes a charged magnetosphere. Currents produced by the bulk motions of the charge distribution determine a field structure typified by a corotating region of field lines which close within the light cylinder and a wind zone defined by the lines of force which cross the light cylinder, and allow charge to flow outwards. But even at points well within the light cylinder the magnetosphere is relativistic, in the sense that the magnetic energy density is much greater than the mass energy density.

When the angle between the magnetic and rotation axes is non-zero, the electromagnetic and plasma fields around the pulsar are non-steady. But it seems inevitable that charges will still be removed from the star, as in the Goldreich and Julian model. The details of the magnetic field structure are less easy to determine than for the axisymmetric case, but Mestel puts forward a qualitatively similar view in which, as for the Goldreich and Julian model, the field obeys the curl free (dipole) approximation to a good accuracy at points well within the light cylinder. For both models, provided that the hydromagnetic condition

$$\mathbf{E} + \frac{\mathbf{V} \times \mathbf{B}}{c} = 0$$

is obeyed, energy outflow occurs only along field lines which cross the speed of light cylinder, and classic magnetic dipole radiation from the curl free zone is suppressed. For a poloidal field the torque will vary as $(\Omega a/c)^{2n-3}$. For a dipole $n=3$, but the work of Pacini and Rees (*Nature*, **226**, 622; 1970) suggests that in the Crab pulsar $n \sim 2.6$, which tends to confirm the non-dipole nature of the energy loss mechanism.

Hy-Ol-Ne diagram it becomes clear that there is no systematic tendency for the non-rise samples to be more alkaline. Furthermore, when the Niggli Quartz Index for each sample—a measure of the amount of silica relative to Al, Fe, Mg, Na and K in the rock—is plotted as a function of distance from the rise it becomes equally apparent that there is no significant tendency for the non-rise basalts to have lower silica saturations. In short, as far as these key parameters are concerned the basalts are indistinguishable. Nor do any differences become apparent when the data are plotted on a silica-alkali diagram of the type used by MacDonald and Katsura (*J. Petrol.*, **5**, 82; 1964) to differentiate between alkaline and tholeiitic basalts in Hawaii.

Bonatti and Fisher interpret this information to mean that both rise and non-rise basalts must be produced within the same depth range, and hence the same pressure range, within the upper mantle. This then implies that the differences in heat flow between the rise region and other areas do not indicate that beneath the rise there is a higher thermal zone which reaches down to the region of magma generation. The heat source which accounts for the higher heat flow must lie above the region of magma production, though it is not immediately clear whether or not such a conclusion conflicts with the simple picture of mantle upwelling at ridges and sinking beneath trenches. An alternative interpretation—that pockets of magma produced beneath the rise are caught in, and spread with, the lower crust only to break through to the surface at a later date—seems to be ruled out by the fact that during the spreading the magma would undergo fractionation and differentiation, processes which would themselves give rise to a compositional difference between rise and non-rise basalts.

PROTEINS

Finding the Way

from our Molecular Biology Correspondent

Arguably the most interesting problem in protein chemistry at present is just how a randomly coiled polypeptide chain finds its way through the almost infinite maze of possible conformational states that it may assume to the haven of the native conformation. It can safely be asserted only that the chain cannot within any reasonable time scale approach it by a process of random wandering, but that there must be pathways determined by the sequence. A widely favoured hypothesis is that the starting points are segments that readily form an ordered structure, such as a few turns of α-helix or a β-fold. This would imply that the parts of the sequence most prone to enter these conformations in the random chain will also be α-helical in the finished article—the folded, rigid globular protein. Scheraga has given arguments, based on the helix-forming potential of particular amino-acids, compared with their occurrence in α-helixes in proteins of known structure, that such is indeed the case. Not even the most sanguine supporters of the theory would claim, however, that the evidence is conclusive, but at present there is no other to which its opponents can rally.

Scheraga and his colleagues are now attempting to place the calculations of helix stability in relation to amino-acid composition on a quantitative basis, and their strategy is outlined in a new series of articles. The stability of an α-helix is defined by two equilibrium constants, σ and s, which define respectively the initiation of an α-helix in a randomly coiled homopolymer chain, and the incorporation of a residue into an existing helix. The well known cooperativity of helix formation and breakdown carries the implication that σ is much the smaller. In homopolymers helix-coil transition profiles can be used to determine both parameths. Von Dreele *et al.* (*Macromolecules*, **4**, 396; 1971) have re-worked the statistical mechanics of the system, with some new approximations, to include polymers containing a proportion of a foreign residue with different σ and s. From the effect of such "guest" residues on the helix-coil transition profile of the "host" polymer, values of the constants can be determined, and Von Dreele *et al.* (*ibid.*, 408) report that for a test case the σ and s values extracted for a given "guest" residue agree well with those determined

Arvin as an Anticoagulant

Fibrinogen is a plasma protein which plays a constitutive and initiative part in the haemostatic mechanism of wound healing. But it is also involved in the formation *in vivo* of fibrin deposits with the grave clinical consequences of disseminated intravascular coagulation, for example, thrombosis and arteriosclerosis. The production of thrombin *in vivo* triggers the following simplified scheme:

$$\overset{\text{Fibrinogen}}{(\mathrm{A}\alpha, \mathrm{B}\beta, \gamma)_2} \xrightarrow[\mathrm{Ca}^{++}]{\text{Thrombin}} \overset{\text{Fibrin clot}}{(\alpha, \beta, \gamma)_p} \xrightarrow[\mathrm{Ca}^{++}]{\text{Factor XIII}} \overset{\text{Crosslinked fibrin clot}}{(\alpha^p, \beta, \gamma^2)_p}$$

where p denotes polymer and factor XIII ≡fibrin stabilizing factor (FSF).

In recent years it has been discovered that certain enzymes from snake venoms can induce formation of fibrin clots from plasma fibrinogen and these clots differ in stability and structure from thrombin-initiated clots. The most used venom enzymes, arvin ('Ancrod') and reptilase, remove only fibrinopeptide A, whereas thrombin removes fibrinopeptides A and B from the Aα and Bβ chains of the fibrinogen molecule respectively. Further differences in the mechanisms of these enzymes are described by Mattock and Esnouf in next Wednesday's *Nature New Biology*. They use the technique of SDS–acrylamide gel electrophoresis to explain at a molecular level the action of arvin as an anticoagulant and thus help to bridge the gap which exists between empirical clinical practice and biochemical rationale.

Mattock and Esnouf corroborate the findings of McKee *et al.* (*Proc. US Nat. Acad. Sci.*, **66**, 738; 1970) that thrombin in the presence of calcium ions activates factor XIII which mediates clot stabilization by the formation of γ chain dimers and α chain complexes of molecular weight in excess of 500,000. They show that reptilase works in a similar manner but in the absence of calcium ions and this would explain its role as a potent topical haemostatic agent. On the other hand, arvin is shown to remove 31,000 molecular weight portions of the α chain with no formation of α chain complexes. It can be suggested that the arvin susceptible areas of the α chains are those which would have taken part in amide cross-linking mediated by factor XIII. Arvin was also shown not to activate factor XIII because very little γ dimers were formed. Non-crosslinked fibrin clots are readily degraded by intrinsic plasmin to soluble non-clottable fibrin degradation products and the role of arvin as an anticoagulant by a defibrination mechanism was demonstrated at a subunit level.

It is interesting to speculate whether arvin might be thrombolytic because Mattock and Esnouf indicate that it degrades the α chain complexes produced by thrombin. Their argument for suggesting that this highly interesting proteolytic activity of arvin could not result from an additional plasmin-like enzyme in the arvin preparation is not supported by the recent evidence that plasmin produces 30,000 molecular weight fragments from the Aα chain of fibrinogen (Gaffney and Dobos, *FEBS Lett.*, **15**, 13; 1971). But in spite of this contradiction, Mattock and Esnouf have amply demonstrated the mechanism by which an arvin preparation acts as a controlled anticoagulant and they illustrate the part that biochemical techniques can play in understanding the principles underlying thrombus formation and dissolution.

directly from measurements on a homopolymer of the "guest" species alone. Ananthanarayanan *et al.* (*ibid.*, 417) have started on the long road to σ and s values for all twenty amino-acids, with glycine as guest (which, because polyglycine is not α-helical, and in any case quite insoluble in water, cannot be examined directly). Glycine turns out by this method to have low s, and should thus function as an α-helix breaking residue, as had been generally supposed.

Lewis, Momany and Scheraga (*Proc. US Nat. Acad. Sci.*, **68**, 2293; 1971) have now considered the β-bend, where a chain folds on itself to form a peptide hydrogen bond between one residue and another four positions along the chain (the third residue being glycine in the best defined form). These folds are relatively common in globular proteins, and Lewis *et al.* have examined a series of proteins of known structure, and worked out the probability that a given amino-acid will be found in each of the four positions defining the β-bend. Armed with these probabilities they have then scrutinized the sequences of other proteins in order to predict where β-bends should occur. Comparison with the X-ray structures showed (depending on how precisely the start of the bend is defined) a moderate correlation between expectation and reality. Of course this suggests only that there are steric preferences for a β-bend, not necessarily that these structures persist the denatured chain. Lewis *et al.* infer, nevertheless, that the bends may be nuclei for folding, and act by bringing remote parts of the chain into appropriate contact.

The experimental approach to the same folding problem has been pressed by Anfinsen and his colleagues. Epstein *et al.* (*J. Mol. Biol.*, **60**, 499; 1971) have now examined further the refolding of staphylococcal nuclease from the acid denatured state. Their handle on the reaction has been the change in fluorescence of the solitary tryptophan residue, which was followed by stopped-flow fluorimetry on neutralization. The reaction, it turns out, can be fitted by two first-order rate processes. The rate constant for the slower process is strongly temperature dependent, that for the faster scarcely at all. The most attractive explanation is that one process consists of the formation of nuclei for the folding, and the other the folding process itself. It is facile, but irresistible, to suggest that the temperature-independent process has the attribute of an entropy-driven nucleation. The scheme is certainly plausible, though it must be recognized that the acid-denatured form of a protein chain will not in general be a true random coil (as, for example, in concentrated guanidine hydrochloride solutions), and must be expected to contain some (though not of course necessarily the right) structural elements. Another facet of the same reaction comes to light in a high-resolution proton magnetic resonance study from the same laboratory (Epstein *et al.*, *Proc. US Nat. Acad. Sci.*, **68**, 2042; 1971). Resonances from the four histidine residues can be individually observed in the native protein, whereas in the acid-denatured state all become environmentally equivalent, and merge into one. For three of the histidines the *p*H profiles are identical, and coincide with that of trytophan fluorescence, but for the fourth there is a biphasic profile. This implies the existence of at least one intermediate, partly folded state in the equilibrium between the native and acid-denatured conformations.

CRYSTAL GROWTH

Origin for Epitaxy

from our Materials Science Correspondent

A RECENT article (S. A. Kobzareva and G. I. Distler, *J. Crystal Growth*, **10**, 269; 1971) adds a further stone to an unusual but increasingly solid edifice built over the past few years by Distler and his colleagues of the Institute of Crystallography in Moscow. Distler claims to have established a hitherto unconsidered origin for epitaxy—that is, the growth of one crystal species on a crystalline substrate of a different species, in an orientation defined by that substrate. He proposes that electric fields emanating from the surface of the substrate control the orientation, size and density of the epitaxial growths. Impressive evidence for this was published some time ago in *Nature* (Distler and Zvyagin, **212**, 807; 1966; Distler and Obronov, **224**, 261; 1969): it was then reported that a sufficiently thin amorphous intermediate layer between substrate and deposit failed to inhibit epitaxy, and furthermore the power to induce epitaxy could be "imprinted" on the amorphous layer (selenium in this instance) by irradiating it before removing it from the substrate. The imprinted amorphous layer, by itself, supported an epitaxial growth of anthraquinone. These results were met by understandable scepticism and at least one investigator failed to reproduce Distler's early findings on the NaCl/amorphous C/gold system, but subsequently C. A. O. Henning (*Nature*, **227**, 1129; 1970) did confirm the findings.

Distler points out that all ionic crystals have charged point defects and assemblies of defects which can under certain circumstances—photoexcitation being particularly favourable—induce substantial permanent dipole moments

---

Composition of Lunar Spinels

WORK on lunar samples has fostered concentrated attention on the nature and properties of several mineral groups, among them the spinels. Lunar samples have been made available to the investigators for limited periods, and rapid publication at conferences and in journals has been encouraged, so as to stimulate discussion and ideas for work on samples for future missions, and perhaps even influence the planning and location of later landings. The publications have thus had more of the flavour of progress reports than is perhaps normal. Each successful mission brings new samples, with additional spinels, so that the reports tend to be cumulative, as indeed is Haggerty's article in next Monday's *Nature Physical Science*. He reviews the compositional features reported by several investigators (including himself) of spinels from Apollo 11 and 12 missions, seeing them in the context of his new results (electron probe analyses) on spinels from Apollo 14 samples.

The major element concentrations in the Apollo 11 and Apollo 12 spinels placed them approximately in the range chromite ($FeCr_2O_4$)-ulvöspinel (Fe_2TiO_4). Apollo 12 spinels occupied each end of the range whereas those from Apollo 11 occupied the middle. Haggerty discusses whether or not this indicates the possibility of a complete range of solid solution, and in order to do this he stresses the roles of magnesium and aluminium which are also present in these spinels.

Haggerty finds that the Apollo 14 samples contain three kinds of spinel, some rather similar to the titanium chromites from Apollo 12, some comparable with the intermediate Cr-Ti spinels from Apollo 11, and some not observed hitherto in lunar samples, which are chromium-bearing members of the series $MgAl_2O_4$-$FeAl_2O_4$. He also uses extrapolations of published thermodynamic data to deduce the minimum oxygen fugacity needed for the stability of each of the spinels, and suggests an increasing fO_2 with falling temperature as crystallization proceeds.

In the absence, so far, of phase equilibrium studies on synthetic spinels of relevant composition, the "circumstantial evidence" of such natural specimens (lunar and terrestrial) as are available is the best guide to chemical relationships. In this situation, however, it is possible that the picture will change somewhat each time more spinels are analysed, particularly if they come from new samples representing possibly different chemical environments.

and consequential fields at the surface. In effect, the crystals contain electrets, the electrical analogue to magnets. Just how the electric fields control the nucleation and growth of epitaxial layers—especially when these are electrically conducting—Distler does not attempt to propose, but it must be admitted that the circumstantial evidence is increasingly compelling.

In the latest article, Kobzareva and Distler make use of a recently established technique to deduce the sign of the local electric field from the local size alignment and packing density of epitaxial anthraquinone crystals on triglycine sulphate (TGS), NaCl and mica (this time without an amorphous barrier). TGS is ferroelectric and so it would be expected readily to "radiate" strong local fields. It was found that on each substrate, two kinds of deposit morphology were found, associated (it is supposed) with positive and negative fields. This hypothesis is reinforced by the direct observation, some time ago, of electrical heterogeneity on a mica surface, using an electrometer, whereas similar heterogeneity was established by an electron microscope technique applied to NaCl (Distler, *Fizika Tverd. Tela*, **11**, 547; 1969). The implication of this latest study, taken together with the earlier ones, is that not only the nucleation but also, to some extent, the growth habit of the epitaxial deposit is controlled by electric fields emanating from the substrate. Distler insists, as he has done in his earlier work, that this makes epitaxial growth strikingly similar to some biological replication process. It now remains to discover how electric fields manage to do it!

FISH BIOLOGY

More about the Eel

by our Marine Vertebrate Correspondent

A RECENT article by E. M. Pantelouris, A. Arnason, and F.-W. Tesch (*Marine Biology*, **9**, 242; 1971), which compares the electrophoretic fractions of esterases, transferrins and haemoglobins in samples of eels from both sides of the North Atlantic, adds a little to the solution of the Atlantic eel "problem". The authors studied samples from Rhode Island and Iceland and their data show both quantitative and qualitative differences between the populations; the qualitative differences are the most striking. The absence of transferrin *D* from the American eels confirms the results of other workers. Furthermore, there are differing electrophoretic mobilities of all fractions making up zones *b* and *c* of the plasma esterases, as well as differences in enzymatic activity and the susceptibility to mercuric chloride of zone *C* of plasma esterases.

Pantelouris and his colleagues note that there were quantitative differences within the samples of the European eel (*Anguilla anguilla*) and speculate that this can be attributed to more than one cause. They suggest that, for example, the European eel may form several subpopulations which are related to different areas of spawning; alternatively, differential selection may distort the phenotype frequencies in which the samples are taken. The authors also note that the unequal susceptibility of certain homologous esterases of mercuric chloride in their samples might be attributable to mercury pollution of the habitat. Pantelouris *et al.* propose to examine this question, and they also plan to test the validity of the differences found between *A. anguilla* and the American eel, *A. rostrata.*

Current interest in the differences between the North American and the European freshwater eels stems largely from the presentation in 1959 by D. W. Tucker of a "New Solution to the Atlantic Eel Problem" (*Nature*, **183**, 495; 1959). Tucker's solution was to suggest that *A. anguilla* and *A. rostrata* are bred of *rostrata* stock in the Sargasso Sea spawning area; all European eels perish before spawning; and such differences in meristic features, such as vertebrae, used by the Dane Johannes Schmidt, and others, to distinguish between the species are caused by changes in water temperature encountered by the larvae at the spawning site. Tucker's hypothesis has gained few serious adherents, but the popular appeal of a "suicide migration" of Europe's eels (to say nothing of the implications for commercial fisheries) has attracted considerable attention.

Before his death, Anton Bruun (*Advances in Marine Biology*, **1**, 137; 1963) had nearly completed a detailed investigation into the chief props of Tucker's theory, and this work shows that the data available do not wholly support Tucker's conclusions. As early as 1961, Gemeroy and Boyden (*Serological Museum Bulletin*, **26**, 7; 1961) had examined the new solution by serological methods and their results show that the sera of eels from North America and Europe differ enough to support the specific distinction between

Flat Revertants Isolated

CELLS transformed by tumour viruses are usually insensitive to density dependent or "contact" inhibition of multiplication; as a result cultures of transformants grow to much higher densities than do cultures of the parental untransformed cells and this phenotypic character of transformed cells forms the basis of methods for their isolation. Not all transformed cells grow to high densities, however, for so-called "flat revertants"—transformed cells which grow to only low saturation densities and in this respect are indistinguishable from untransformed cells—have been selected from populations of typical high density transformants. And now Scher and Nelson-Rees describe in next week's *Nature New Biology* a method for isolating directly SV40 transformed 3T3 cells which grow only to low saturation densities. Furthermore, they have shown that these cells grow only to low densities not because they have retained their susceptibility to "contact inhibition" but because at confluence the cells die as fast as they divide.

Scher and Nelson-Rees's technique is simply to select from cultures of mouse 3T3 cells infected by SV40 those cells that are able to grow in media which lack the serum factors required for the survival and proliferation of untransformed 3T3 cells. Having isolated in this way transformants which do not depend on serum factors, they then measured their saturation densities; most clones grew to densities between 2.5 and 10.5-fold greater than untransformed 3T3 cells, but about 15 per cent of the transformed cell clones grew only to the same density as the parental cells.

In an attempt to explain the unusual behaviour of these "flat" transformants, Scher and Nelson-Rees measured their ability to incorporate thymidine into DNA and the extent of mitosis in confluent cultures. They found during a two day period between 50 and 70 per cent of the "flat" transformant cells make DNA and during a 60 hour period about 50 per cent of the cells divide. By contrast, less than 1 per cent of a confluent culture of untransformed 3T3 cells divides during 60 hours. Clearly therefore these "flat" transformants continue to divide at confluence even though the number of cells in the culture does not increase significantly. Cells must therefore be dying at about the same rate as they are multiplying. An analysis of the chromosomal complement of these directly isolated "flat" transformants reveals that although several lines have more chromosomes than the parental cells, at least two have about the same number of chromosomes as the parental cells.

These experiments once again draw attention to the fact that the phenotypic characters used to diagnose viral transformation can be dissociated from one another. They also rub home the lesson that cells may grow to only low saturation densities for reasons other than susceptibility to "contact" or density dependent inhibition of division.

the species. So different are they in fact that they approach the limits of intrageneric relationship when compared with other fish taxa. This recent article by Pantelouris *et al.* and the substantial body of literature on eels that has accumulated since 1959 all tend to support Schmidt's classical hypothesis.

ULTRASONICS

Recent Applications

from a Correspondent

THE "Ultrasonics 1971" conference and exhibition was held in London on September 28 and 29 and was the seventh of the series organized by the journal *Ultrasonics*.

On the opening morning, the session on underwater sound was notable for an account by Professor W. D. Chesterman and Dr J. C. Hopkins (Bath University of Technology) of the recording of side-scan sonar signals on magnetic tape—to be replayed later under controlled conditions or into an oscillograph system so that the pictures can be filmed to give true-to-scale survey records. In a fascinating contribution, Dr R. W. G. Haslett (Kelvin Hughes Ltd, Ilford) described the use of sound in fishing and indicated how model investigations on the echoes could be correlated with the average size and shape of fish in a shoal.

Drs M. Topp and P. Eisenklam (Imperial College, London) drew attention to the importance of ultrasonic atomizers in oil burners, as medical nebulizers, as metal sprayers and the like; their use in Britain is, however, not extensive. Ultrasonic atomizers derive their power from magnetostrictive transducers (20 to 125 kHz) or piezoelectric transducers (30 kHz to 5 MHz). One such ultrasonic atomizer involves an angular bowl-shaped concentrator which is capable of atomizing a 100 μm sheet of solid aluminium placed across the mouth, using only a 100 W generator. Although ultrasonic cavitation produces much more drastic effects in polymer solutions than other degradation techniques, Dr P. Vaughan (Letchworth College, Hertfordshire) emphasized that such processing by ultrasound still remains a research undertaking. In the biological field, Drs W. I. Coakley and C. J. James (University College, Cardiff) spoke on the activity of enzymes released from yeast by sonification. They showed that the rate constant for enzymatic denaturation is dependent on the protein concentration and that for optimum results the cell concentration should be high.

In the afternoon session certain general aspects of ultrasonic testing were considered and there was one very significant contribution by Drs E. E. Aldridge and H. G. Tattersall (NDT Centre, AERE, Harwell, who have developed the idea that use could be made of the ultrasound radiation scattered from the main wave. Although in general this radiation will not give an absolute measure of the macrostructure of the medium, it can yield useful results when correlated with other relevant information.

High power ultrasonics has come into prominence again and was the theme of one of the parallel morning sessions of the second day; two of the subjects dealt with concerned transducers (Dr R. R. Whymark, Interand Corporation, Chicago, and Dr E. A. Neppiras, University of Houston). Dr B. Largenecker (PVC Laboratory, Waldbach, Austria) showed how the application of high amplitude ultrasound reduces the external stress necessary for plastic deformation; he has made a notable contribution to the design of machines for drawing brittle materials. The second of the morning sessions was devoted to the fast growing field of medical ultrasonics. Outstanding in this section was the talk by Dr M. K. Patrick (Birmingham General Hospital) on her experience with ultrasonic therapy in clinical practice.

The final session in the afternoon of September 29 was concerned with automated non-destructive testing and the last contributions were from Drs V. M. Barborovsky and D. Marsh (Tube Investments Research Laboratories, Cambridge) on a Schlieren study of ultrasonic pulse propagation and reflexion. The aim of the work was to simulate the detection of cracks in steel tubes and thus to improve the reliability of the test method. Glass models were used in the Schlieren system to provide a transparent medium, ultrasonically very similar to steel. The pulsed light source has to satisfy the condition that its flash duration time was short compared with the period of the ultrasonic wave and a new version of the argon jet source was found to be very suitable. The apparatus had to be carefully designed for vibration isolation because the deflected light from the phase-diffraction grating, formed by the ultrasonic pulse train, gave diffraction maxima separated by only 66 arcsec from the undeflected light using sheer waves of frequency 2 MHz.

Recognition Sites for tRNA Charging Enzymes

IN *Nature New/Biology* next Wednesday, Squires and Carbon report a series of experiments which shed new light on the intriguing question of how the different species of transfer RNAs are recognized and distinguished by their specific amino-acyl tRNA synthetases, the enzymes which charge tRNA molecules with amino-acids. And into the bargain Squires and Carbon report the location on the *Escherichia coli* genetic map of the third species of glycine tRNA, $tRNA^{Gly}_3$, which translates the glycine codons GGU/C.

Squires and Carbon found that a mutant strain of *E. coli* which lacks about one-third of the amount of $tRNA^{Gly}_3$ present in wild type cells contains a new species of glycine transfer RNA, designated $tRNA^{Gly}_{ins}$, which can translate the codons GGA/G. This mutated form of glycine transfer RNA maps at about 86 minutes on the circular *E. coli* genetic map and experiments with diploid and merodiploid cells prove that this is the position of the structural gene, or rather genes for $tRNA^{Gly}_3$, of which there must be multiple copies in each wild type genome.

To prove that $tRNA^{Gly}_{ins}$ appears as a result of a mutation in one of the $tRNA^{Gly}_3$ structural genes, Squires and Carbon analysed the base sequences of the two molecules and found that they differ in only one position; the anticodon sequence of $tRNA^{Gly}_3$ is GCC and that of $tRNA^{Gly}_{ins}$ is UCC, but apart from this G→U base change in the third or "wobble" position of the anticodon the two molecules are identical.

Glycyl tRNA synthetase charges the mutated $tRNA^{Gly}_{ins}$ at about the same rate as $tRNA^{Gly}_3$. By contrast, Carbon and his colleagues, working with wild type and mutated forms of the two other species of glycine tRNAs ($tRNA^{Gly}_1$ and $tRNA^{Gly}_2$) in *E. coli*, have found that changes in either the first or second base of the anticodon drastically impair the recognition of these molecules by the glycine charging enzyme. They conclude therefore that the first two bases but not the third "wobble" base are involved in the interaction between glycyl tRNA synthetase and the glycine tRNAs.

Squires and Carbon also noticed that the base sequence of $tRNA^{Gly}_3$ is very similar to that of the valine tRNA, $tRNA^{Val}_{2B}$, which was analysed by Yaniv and Barrell. 78 per cent of the sequences of these two tRNAs are, in effect, identical and what few differences there are between the two molecules are to be found in their hydrogen bonded stems rather than their single-stranded loops. It seems therefore that the base sequences of these double-helical stems provide recognition signals which allow the glycyl and valyl tRNA synthetases to distinguish their respective tRNAs. Whether, however, this is a general rule, and the hydrogen bonded stems of all tRNAs provide recognition signals for their respective synthetases, remains very much an open question.

Aeronautics before 1919

GEOFFREY TAYLOR
Trinity College, Cambridge

Professor Taylor describes his aeronautical experiences during the First World War and just afterwards.

I HAD studied fluid dynamics as a student and was applying my knowledge to meteorology when the First World War started on August 4, 1918. Like most of my friends, I volunteered for service in the army and suggested that I might set up a weather forecasting unit in the field. The officer to whom I made this proposal did not seem to doubt that I could tell what the weather was going to be—as he might very well have done—but thought the knowledge would be of no value to the army in the field. "Soldiers don't go into battle under umbrellas, they go whether it is raining or not," was his comment. I expected then to join a combatant unit, but I left my home address in London with the officer I had interviewed in case the army had any use for the services of a scientist.

On the evening of August 5 a message came from Major Sefton Brancker, then the head of the flying wing of the army, that the Royal Aircraft Factory at Farnborough would employ me as a scientist if I offered my services in that capacity. I went there the next day and the Superintendent, Mervyn O'Gorman, introduced me to a fascinating character, Teddy Busk, who invited me to live in the Naval Airship Mess where he lived himself. Busk was perhaps the first man to make a practical study of the stability, as distinct from the controllability, of airplanes. The machine which he designed to be stable, BE2C, could be flown without hand control and a thorough study of its aerodynamic character was being made when I began work in Farnborough.

Designing Darts

My first flight in an airplane was with Teddy on November 4, 1914, in the prototype BE2C, in which he was measuring the periods and decay times of longitudinal oscillations. The next day he was continuing his experiments on the same machine when it caught fire in the air and he was killed. During my flight with him I had noticed a strong smell of gasoline and he had explained that the carburettor was supplied from a small gravity feed tank in front of the passenger's seat. At frequent intervals this had to be filled by the pilot, who pumped gasoline from a larger tank under his seat. Unfortunately there was no indicator to show the pilot when the small tank was full and gasoline poured onto the passenger's seat if pumping was not stopped in time.

The asylum for theoreticians to which I was assigned when I arrived at Farnborough was called H department. I never knew what H stood for, but it tackled odd jobs which the engineers did not care about. One job which was assigned to Melvill Jones and myself illustrates the kind of thought which prevailed at that time. The French had been dropping pointed darts called *flechettes* on troops from their planes. It was found that these whirled when dropped, even though they would point into the wind when suspended at their centre of gravity, and we were asked to design one which would fall straight. We pointed out that a bomb which projects its fragments horizontally would have a much better chance of hitting troops than darts coming vertically, but it seemed a matter of prestige that we should have our own dart and that it should be better than the French dart, so we took on the job of designing one. After we had done this we took a few hundred of them in a satchel up a steel ladder inside a disused tall chimney so that we could watch them from above as they fell. They flew quite straight.

Having designed the dart, we were asked whether the terminal velocity in free flight was big enough to damage troops, so we bored out a rifle barrel and shot the darts with reduced charge at a leg of mutton hanging as a ballistic pendulum so that we could find out the impact speed and correlate it with penetration. Finally, we were asked how the darts would spread if a bundle of them were dropped from a plane. To answer this we got a pilot to throw a few hundred over a field from a height of several hundred feet. When this had been done, Melvill Jones and I went over the field and pushed a square of paper over every dart we could find sticking out of the ground. When we had gone over the field in this way and were looking at the distibution, a cavalry officer came up on his horse and asked us what we were doing. When we explained that the darts had been dropped from an airplane, he looked at them and seeing a dart piercing each sheet remarked: "If I had not seen it with my own eyes I would never have believed it possible to make such good shooting from the air".

The darts were, however, never used, but not apparently for the reason we had originally raised as an objection—that they would be inefficient; we were told they were regarded as inhuman weapons and could not be used by gentlemen.

Learning to Fly

After I had been employed for a short time designing instruments for use in the air, I felt that I might be able to do a better job if I were taught to fly myself. When I put that point of view to O'Gorman he agreed with me, but the army refused to sanction the proposal that a scientist should be taught to fly. They told me that I only had to ask a pilot and he would tell me anything I needed to know. The fact was that pilots usually did not understand the physical causes of the sensations they experienced while flying and told, as facts, their interpretations of the causes of their sensations. O'Gorman was, however, clever at getting his way by devious schemes. He allowed me to resign from his factory so that I would be free to apply for training as an uncommitted citizen, and said he would apply for me to return to Farnborough when I had passed through the flying training school. In May 1915 I went to the school which used the space in the middle of the old Brooklands motor racing track as an airfield. I started to learn on the 1913 model Mawrice Farman biplane, then called a longhorn or Rumpety. This plane looked old fashioned but was a good training machine. Its maximum level speed was about 60 m.p.h. and it was said to stall at about 37 m.p.h. We aimed to land it at 42 m.p.h. Though the engine frequently gave out in the air, its low landing speed made it possible to land safely in many grass fields. Also, if it did crash, the staging supporting the elevator in front could act as a shock absorber. These machines were held together with piano wires, and so many were needed that the mechanics used to say that when they erected the machine they released a canary between the wings—if it got out, a wire was missing. My instructor was a flight sergeant who had been damaged in a crash caused by one of his pupils. He decided this must not happen again, so if any of them exerted any appreciable force on the dual control column he reported they were heavy handed and would never make good pilots. As very few machines were then available for training and many people wanted to join the air service, the threat that one would be turned out was to be avoided at all costs and many of this man's pupils took over control of their machines for the first time on their first solo flight. The resulting erratic manoeuvres were sometimes spectacular. I came through better than most because of the months I had spent at Farnborough; at least I knew what the controls were supposed to do.

The course at Brooklands provided a restful interval in an otherwise restless world. We would go early onto the field and, if there was more wind than would put a match out, flying was cancelled and we would go home, though we had to keep a watchful eye in case the weather improved.

When I graduated as a pilot in July 1915, I was sent on a course described as "artillery spotting". We were instructed to observe a certain farm which was marked on a map. People on the ground let off smoke puffs and we had to tap a key screwed onto the cockpit and give in Morse code the distance and bearing of the smoke puff from the farm. Wireless telephony had not then been invented and it was necessary to unwind a weighted aerial while in the air. I failed on my first try because I forgot to wind the aerial in after finishing the test, and dragged it off in a hedge on the perimeter of the field as I approached to land.

Wings and Airscrews

In the early days of the First World War the engineers had no confidence in the theorists because mathematical predictions about the forces on moving bodies never seemed to give experimentally verifiable results. Prandtl's boundary layer theory had not yet been developed or at any rate had not penetrated to Farnborough, and designers could only rely on wind tunnel tests with models to give them design data. Even the applicability of model data to full scale situations was doubted, chiefly because very few measurements which could be compared with calculations had been made on full scale airplanes. For this reason the first thing I did when I returned to Farnborough after passing out from the flying school was to look for something which could be measured both on a model in a wind tunnel and also in flight on a full scale airplane. The weight of the plane was known and this could be correlated with model lift measurements in wind tunnels, but the same method could not be used for measuring drag because nothing was then known about the efficiency of the engine–airscrew combination. I decided to try to measure the distribution of pressure over one section of the wing of the BE2C plane which had been allotted to me for the purpose. I got the workshops to construct a wing with twenty holes spaced round a section and I connected them through copper tubes to a manometer in the cockpit. I was to be alone in the plane, so I had to design a manometer which I could operate while I was flying. Fortunately, the BE2C was a completely stable machine, for I had to fly at a fixed speed for some time to get the manometer steady before pressing a button which photographed the manometer tubes. The results were given in non-dimensional form as $p/\rho v^2$ for the range of speeds at which the BE2C was capable of level flight, namely 50 to 90 m.p.h. When these curves were compared with wind tunnel measurements made at the National Physical Laboratory (NPL) the agreement was not good, but it was found that the NPL had not made a proper correction for the effect of the tunnel walls, and when this was done the agreement was very good. I published the results in 1916 and they may have been the first full scale pressure distribution measurements, though many have been made since.

One of the problems which was tackled at Farnborough in those days was that of setting up a theory of airscrews. Their sections were airfoils and very soon it was found that if the wind tunnel data for each section of the blade were applied as though it were advancing into still air, the calculated result did not agree with measurements made on a test bench. On the other hand, the results could be correlated if it were assumed that the air approaching the airscrew was already in rotation before it reached the plane of the screw. Thus they introduced a fictitious rotational inflow factor which made the calculations agree with observation. This shocked me, because Lord Kelvin had already shown that circulation cannot be produced by the pressure variations that might arise from the motion of the blades and I wrote a note pointing this out. Shortly afterwards, H. Glauert cleared up the difficulty and showed that though the circulation in the approaching ring of air was in fact zero, the direction of the air approaching each blade was changed because of the pressure field produced by all the other blades. Thus the air in the field close to the front of each blade deviates in one direction and the air approaching the spaces between the blades is deviated in the opposite direction, making the total circulation in rings of air approaching the airscrew zero. This example is interesting because it illustrates the condition under which correct conclusions about aeronautical situations can be based on the classical theory of non-viscous fluids. The forces on bodies moving steadily through the air are due to the viscosity of air and the mechanism of the process is described by the viscous boundary layer theory, but when a fluid is moved only by a pressure gradient without the intervention of viscous effects, circulation—that is, the integral of the tangential component of velocity round any circuit of fluid particles—cannot be produced.

Though most of my work in the air was carried out with the stable BE2C, which was controlled laterally by means of ailerons, I flew two machines which had no ailerons and were controlled by warping the whole wing; wings in those days were not the rigid constructions one sees now. This method of control worked satisfactorily when the air was calm but it was exceedingly uncomfortable under bumpy conditions. The reason for this behaviour was that the control wires had to move the whole wing, not just the much smaller aileron. When flying straight in bumpy conditions it was impossible to prevent violent lateral motions of the stick. In spite of this wild waving of the control stick, it only needed a small steady force to make a turn.

Indicating the Vertical

One of the great difficulties in flying at that time was that as soon as one got into a cloud and could no longer see a horizon one had no means of appreciating the vertical direction and pilots often came out of clouds in steep banks thinking they were still horizontal. Some instrument was needed to tell whether one was turning. Gyroscopes had not yet been designed for use in airplanes and some instrument was needed to tell pilots whether they were turning. One was invented by Horace Darwin, a son of Charles Darwin, who had noticed that it would be useless to fit pitot tubes at each wing-tip to measure the difference in velocity during a turn because the pressure difference in the pitots would be balanced by the pressure difference due to centrifugal force in the tubes connecting them with a manometer in the cockpit. On the other hand, if static pressure heads were substituted for pitot tubes, the pressure change in the tubes from the wing-tips to the cockpit would constitute a potential turn indicator. The instrument constructed on this principle made it possible to fly safely through clouds and at night. Of course, people had flown through clouds before turn indicators were invented but few would fly continuously without the visual aid of a horizon. So well was this difficulty publicized that it required quite a group of inverted Micawbers to turn down the ideas of people who invented instruments for indicating the vertical.

The ability to fly at night had not made it possible to undertake night bombing except on very clear nights when land features could be seen all along the route, and on such occasions people did not want to fly over enemy territory. In 1918, Bertram Hopkinson invented a simple method for night bombing at the small distances over which one might assume a constant wind. This entailed the shining of two searchlights vertically from points about a mile apart on the line to the target. On most nights there was enough haze to show up the vertical beams and the pilot manoeuvred his plane into line with them and found the compass bearing on which they kept in line as he approached. He then flew on this bearing through both beams. On passing the first he started a stop-watch which he read on passing the second; then, knowing the ratio of the distance of the objective to the distance between the lights, he flew on the same compass course for a time equal to that ratio multiplied by time between his passages over the two searchlights. The method was not actually used but the required equipment was set up and was to be used for the first time on a certain evening for bombing Coblenz from a point in the American section of the Front near Colombé, but peace broke out on the very day before the exercise was to be performed.

Crossing the Atlantic

At the end of the war the *Daily Mail* offered a prize of £10,000 for the first non-stop flight across the Atlantic. Four firms entered machines which they had designed during the war, adding extra fuel tanks for the competition. I went with the Handley Page party, partly as meteorologist and partly to teach the navigator, Tryggve Gran, some celestial navigation. It was not practical to set out for Newfoundland until the worst of the winter was over because there were no airfields there and the ground would be very soggy. The four firms which competed—Vickers, Handley Page, Martinsyde and Sopwith—sent their expeditions at about the same time. Though I suppose they each expected to gain some commercial advantage, the competition was essentially a sporting event. We each had to make our own airfields and erect our machines in the open. As soon as we landed from the ships which had taken the expeditions to Newfoundland we each chose a piece of land to make into an airfield. Vickers made theirs on high ground behind St Johns. Martinsyde opted for a place called Quidi Vidi Cove, just north of St Johns, and Handley Page chose a field at Harbour Grace about 60 miles from St Johns. Until our move to Harbour Grace all the expeditions lived in the one decent hotel in St Johns and every morning we went off early to the chosen sites of our airfields and worked furiously to try to get going before the other competitors.

The first competitors to try their luck were the Martinsyde group. They had loaded their machine too heavily, I think, and it crashed before it became airborne. The navigator, a man called Morgan, was hurt, and when this news became public, would-be navigators rushed to St Johns from all over the world; one, I remember, came from Argentina. The next to try was the Sopwith, with Hawker as pilot and McKenzie Greave as navigator. I saw them take off and we had no news of them for nearly two weeks. Then they turned up in a Scandinavian freighter which had no radio.

The third to take off was the Vickers, with Alcock as pilot and Brown as navigator. As everyone knows, they got across and crash-landed in a bog in Ireland. Brown pretended to be quite ignorant of navigation, though that must have been a pose. I remember asking him how he would know where he was when he saw Europe beneath him. His reply was, "I will come down and if I see people in Mantillas I will know it is Spain. If I see people eating frogs I will know it is France and if I see them hitting one another over the head I'll know it's Ireland." When the Vickers took off I was standing near the machine when it started. I saw it run the full length of the airfield and disappear below the level of the high ground on which I was standing. We all thought it must have crashed because of excessive loading, but after a few minutes it came back, having climbed about 100 feet, and shot straight out to sea. The Handley Page machine was bigger than the others and took longer to erect; it was just doing its test flights when Brown and Alcock got across, so it very wisely turned south for New York.

The Perennial Dilemma of Science Policy

Pure Chemistry Library
SCIENCE COLLEGE.
92 Upper Circular Road
CALCUTTA

PAUL GARY WERSKEY

Science Studies Unit, University of Edinburgh

". . . Science on the scale it is pursued today is an integral part of the social organization of the State. Wherever he works, the man of science is a part of the machinery of State, and there is no real immunity of science from its political environment." *Nature* had much to say on the organization of science between the two world wars.

THE period between the two world wars was notable in the history of science, because it witnessed not only important discoveries in the laboratory but the first attempts in Britain, Russia and elsewhere to establish national science policies as well. From its vantage point in the United Kingdom, *Nature* kept a hopeful but watchful eye on these new experiments in the organization of research. The journal's editor, Sir Richard Gregory, was of course favourably predisposed to any action which would increase the influence of science and scientists in public affairs[3]. On the other hand, he recognized that the state could encroach too far on the traditional autonomy of "pure" scientists[4]. *Nature* thus demanded of government-science relations a balance between apparently conflicting demands for the scientists' involvement with and detachment from social needs.

How such an equilibrium could be established in practice was a topic then frequently discussed in *Nature*'s leading articles[5]. (Many of these were unsigned, but the authors' names were recorded on one set of volumes of *Nature*, which has been used in the preparation of this article.) Having committed itself to the ideal of "an accepted national scientific policy, definite, continuous and consistent"[6], the journal was forced to construct a workable model for the conduct of research in a socio-political context. Unfortunately, the discursiveness of the leader columns defeated any attempt to outline a complete solution to such a novel and complex problem as "planned" science. What the articles sought instead were answers to more specific questions. How much of scientific activity can be consciously organized? What priorities and which social groups ought to govern the funding and administration of research programmes? Finally, would such a policy conflict with established professional values and/or introduce new ones? *Nature*'s model for a national science policy must therefore be intuited from its views on these subjects.

The Model

Under Gregory's auspices, *Nature*'s commitment to the concept of a national science policy begins with the assumption that science as a social phenomenon is susceptible to some form of planning. Clarity on this point demands a distinction between the planning for science and the planning of science. (Graham uses this distinction in ref. 7.) The former notion suggests that, first, the rate of scientific development can be influenced by the size of the human and capital resources allocated to research, and, second, that specific areas of investigation can be encouraged through preferential treatment. The journal's leaders in this period are sensitive to both possibilities. They argue that the combination of adequate educational opportunities and generous research grants will result in a considerable growth of the scientific community. To make the most effective use of scientists' talents, facilities must be provided for: pure basic research in the universities; applied basic research in government laboratories, independent research institutes, and industrial research associations; and, finally, technological innovations at the industrial level. Sir Richard and his associates further recognize that the knowledge derived from such operations cannot be of use unless it is efficiently disseminated. Some liaison between different kinds of investigators, as well as a rational system of publication and data storage, are therefore required. Once such resources are made available it becomes possible to aid those fields of research which merit special attention. The growing points of important theoretical sciences are obvious candidates on intrinsic grounds alone, as are the borderline areas between well established disciplines, that is biophysics, biochemistry and physical chemistry[8,9]. In the cases of applied basic research and technological innovation, *Nature* concedes that extrinsic factors must predominate. The studies of the properties of dyestuffs, nutrition and aerodynamics ought to be supported primarily on the grounds of their economic, medical or military utility. In short, planning for science can assist in both the growth of knowledge and the solution of social problems.

While editorials assert that the organization of research can be moulded at the macro-level, they are reticent to suggest innovations within the laboratory itself. "The scientific investigator," writes Gregory in 1916, "must have freedom to follow his own course wherever it may lead, whereas technical research can be organized and definite problems presented for which solutions of direct service are sought"[10]. The latter group is therefore counselled that "though they may regret the gradual encroachment of bureaucracy on the freedom of scientific investigation, (they) have to recognize that they are primarily public servants whose first duty is to perform their allotted tasks in the social machine"[11]. Pure scientists, by contrast, are exonerated from attempts to have their work organized for them. "Such a proceeding would be repugnant to the best research workers"[12].

To preserve science's subtlety and sophistication at the micro-level, Gregory and his colleagues reason that the administration of science policy should largely be the responsibility of scientists. They naturally recognize the right of any government to oversee the operations which it finances[19,14]. In practice, though, the leading articles urge that "... scientific men should decide upon the allocation of funds for research ...; and ... they should be responsible for any schemes of organized investigation. Friction and misunderstanding always arise when these functions are performed by official administrators unfamiliar with such a sensitive plant as scientific genius and unable to judge the promise of incipient inquiry"[15].

Nature extends this rationale to applied basic research as well as to theoretical investigations. When it is recalled that funding for the former area ought to be based on socio-economic needs, it is clear that scientists, according to *Nature*, must have more to contribute to policy than just their technical competence. Gregory's writers, especially Rainald Brightman (an ICI librarian), believe that the scientific outlook of certain researchers allows them to view society more objectively than many non-scientists. Therefore, as Sir Richard himself points out, "Many scientific workers ... are no longer content to be regarded as hewers of wood and drawers of water ... They know how science enters into every department of national life or international undertaking, and they claim to be entrusted with a reasonable share of responsible control of the forces created by them"[16]. The political overtones of such a position are clear enough[5]. Scientists themselves should determine not only the scientific criteria but also to some extent the social priorities which govern a nation's science policy.

The professional implications of *Nature*'s "model" for a national science policy are thus of critical importance in at least three areas: international cooperation, freedom of research and social values. (M. King[17] has analysed Gregory's reflexions on professional values from a sociological perspective.) Science as a profession has long prided itself on its ability "to be truly international and capable of transcending national follies"[18]. Once scientists are organized along national lines, however, a potential constraint on such internationalism is introduced. State responsibility for scientific development may also limit another constituent of science's traditional ethos, the operational autonomy of individual researchers. Brightman, for example, grants that "the right of society in a time of emergency to prescribe the directions in which scientific effort shall first be made can scarcely be challenged"[19]. One such crisis would be the mobilization of a country for a war in which science would play a major role. In the absence of a system in which scientists are integrated into the machinery of government, it would be plausible to state that the use of research for destructive purposes "is not a question for science but for the public and its leaders"[20]. The foundation of a national science policy, however, introduces this ethical dilemma into the scientific profession. As Gregory concedes in 1938, science can no longer "be divorced from ethics, or rightly absolve itself from the human responsibilities in the application of its discoveries to destructive purposes in war or economic disturbance in times of peace"[21]. If scientists are the chief architects of policy, then the issue of social responsibility is only further intensified.

Nature therefore advances the theory of a science policy which, if realized, would perhaps modify certain well established values of the scientific profession. In the minds of Gregory and Brightman such a programme would minister to both the needs of science and society far more effectively than the disorganized "system" extant at the end of the First World War. The ICI librarian could accordingly proclaim in an important leader of 1934 that: "The conception of science as a social function intimately linked up with human history and human destiny, moulding and being moulded by social forces, should summon forth from scientific workers something of the energy required to translate into policy and action the knowledge acquired by their work. Such energy will find its expression ... in ... the faith that human reason by using wisely the scientific method can give us the control of our destiny"[22]. On these grounds, how did the journal judge of the uses which Britain and other countries made of science and scientists between the wars?

Science Policies, 1919–1938

Nature was not happy with the organization of research in any country during this period. In Britain successive governments were berated for their failure to mould a number of autonomous research facilities into "a national research organization commensurate with our needs ..."[23]. Brightman went on to complain in 1933 that: "If there has been little attempt to rationalize even the grants made by Government to particular fields of research, there has been no attempt as yet to assess the place of research in the broadest sense in the structure of our national life—to evaluate its contribution in each department of State as well as in industry, to assess the relations of fundamental and applied research on a systematic and thoroughgoing basis and to correlate the contributions from the national exchequer and those from industrial and private sources"[23].

So uncoordinated were the financial procedures of the state's various scientific agencies that "Parliament is not in a position to ascertain with ease the total assistance it is granting to one institution . . ."[24]. There is thus little to wonder at in a Brightman leader of 1937 which states: ". . . we have reached a stage when it is imperative to take stock of the nation's resources and facilities for research, both academic and industrial"[25].

The journal's own stocktaking revealed a number of weaknesses in the national structure of research. For example, *Nature* was convinced that the number of biological and social scientists was grossly inadequate for the needs of either the nation or the British Empire[26]. Several factors were cited as contributing to this deficiency, but the primary one was the neglect of biology and sociology in the curricula of elementary and secondary schools[27]. (*Nature* welcomed the later increase in the number of school certificate examinations in biology[28].) An even more serious problem was the inability of government, industry and the universities to fashion any effective liaison between basic researchers and technologists. "We are still without a real technique of discovery, and important industrial developments as often as not are based on purely fortuitous discoveries"[29]. To remedy such a state of affairs the journal tentatively presented in 1927 a case for the nationalization of industrial research facilities[30], but such a notion was explicitly rejected by Brightman four years later[31]. As for the universities, *Nature* was undecided as to whether they should either spurn the advances of industry[32] or welcome new opportunities for applied research[33]. The journal, unable to formulate a programme for structural change in this area, had to content itself with the plea for an increase in the resources devoted to technological development. In essence, existing administrative techniques would not permit the realization of an important aspect of the science policy model. Whatever hopes Gregory, Brightman and others entertained for the growth of science in national life were therefore ultimately based on the lone fact that "Scientific men are now in real control of scientific policy in Britain, even when it deals with enterprises endowed by the State"[34].

If *Nature* was dissatisfied with the disorganization of research in the United Kingdom, it was horrified by the relatively complete integration of scientists into the differing political systems of Germany and the Soviet Union. Gregory's first concern was that the fervent nationalism which informed the science policy of the two countries was inimical to the maintenance of an international scientific community. The First World War had of course already introduced the first serious frustration of science's traditional internationalism: ". . . for the first time scientific men themselves were brought into the conflict instead of continuing quietly to work in their laboratories, and maintaining correspondence with those of other nationalities, as was formerly the case"[35]. After Germany had become the first nation to utilize laboratory-produced poisonous gases on the battle fields, leaders of research from the allied countries decided to found new international scientific institutions which would exclude German scientists. *Nature*, with an editor who said in a letter to H. G. Wells in 1918 that he was "'bitter against the Germans at having caused the present war'", supported such a policy of estrangement. Sir William Tilden thus demanded in a leader of 1919 that all international associations "must be freed from German membership and influence and to accomplish this . . . new and independent associations must be formed by the Allies, together with such neutral Powers as, after deliberation, choose to dissociate themselves from Teutonic combinations"[60]. Having witnessed and participated in this initial dimming of the international spirit, *Nature* was thereafter extremely sensitive to any further outbreaks of nationalism. Germany was of course brought back into the official life of international science just in time for Hitler to use various science congresses as platforms for Nazi propaganda. From the first, Gregory and his associates were opposed to the Fascists on political grounds alone[37]. When the Nazis attempted "to secure the control of international scientific work", the journal urged that "it is time to call a halt"[38]. Russia was subjected to similar criticism[39], even though it had effected a great part of the science policy model which *Nature* supported (ref. 7, especially Chapter 2).

The science policies of the Fascists and Communists were also rejected for their conscious curtailment of the intellectual freedom of individual scientists. Gregory himself noted of Hitler's Germany that "what seems to men of science most deplorable is the elevation of a national passion into a principle, the acceptance of a policy which teaches that to attempt to find and hold truth is but a secondary and subordinate activity of the human mind to be postponed or slighted for *any* reason whatever"[40]. The specious racial theories used by the Nazis to justify the dismissal of Jews from the universities inevitably incensed the *Nature* coterie[41]. After four years of repeated attacks on Hitler's regime, the journal was, not surprisingly, banned from Germany[42]. The Soviet Union also earned Gregory's displeasure, because of its apparent subordination of science to the demands of Marxist dialecticians. Thus in an article of 1921 an emigré Russian scientist styled the Bolsheviks as "men of simplified views—doctrinaires and politicians—they cannot accept the fact that science must be independent of everybody and everything. They think it quite right and advisable to make scientific men 'obedient' executors of the commands of the Soviet Government"[43]. In the 1930s *Nature*'s views on Russia, although expressed less vehemently, altered very little. To take one example, a leader of 1937 pointed to Lysenko's initial harassment of well-known orthodox geneticists as an illustration of "the atmosphere in which scientific investigators in totalitarian countries have to live and work"[44]. In its equation of the threats posed by Hitler and Stalin to the internationalism and freedom of science, *Nature* was led to support the exclusion of both their respective nations from the councils of world science "on the ground that in these countries at present scientific workers are bound much more closely to their respective Governments than is the case elsewhere"[45].

The difficult relations between various national scientific communities were, however, only one aspect of a progressive deterioration in international relations during the 1930s. As the prospect of war increased, so too did the defence budgets of the European powers, including Britain. *Nature* now feared that even in the United Kingdom "the intensification of preparations for self-defence has tended to strengthen the fetters on freedom of investigation and exposition which dictatorships in many countries have already riveted on industrial and academic workers alike"[46]. If rearmament threatened to tie working scientists too closely to the government, then it stood doubly condemned because of its inherently destructive purpose. Gregory hypothesized in 1938 that "when the object of research is the command of natural forces, without regard to their relation to human life, it can become a social danger and an excuse for scientific barbarity"[47]. Should the scientific worker therefore contribute his talents to an enterprise which might threaten the life of both science and society? *Nature* was not at all certain, at least until 1938. Thus: "Already in the time of the Great War the prostitution of science to warfare was deeply felt by many British men of science, some of whom refused altogether to participate either as soldiers or as scientific workers. The same attitude would again be taken by many, should we be cursed by another war; even in the present time of uneasy peace, the activity in rearmament is renewing in the minds of many men of science the same tension of feeling, the same problems of conscience"[48].

Conflict and Resolution

The perversity of international politics in the 1930s thus elicited in the most unfortunate circumstances the three challenges to professional values implicit in *Nature*'s model for a national science policy. As Gregory's and Brightman's awareness "of the extent to which political organizations can affect the direction of scientific research, and even frustrate its efforts"[49] increased, their interest in the extension of the state's responsibility for science diminished. The journal went so far as to petition its scientist-readers in July 1938 not "to allow any external system of thought or institution to dictate their decisions or activities . . ."[50]. Strict adherence to such an injunction would of course have reduced any conception of national planning for science to a level of theoretical and practical absurdity. For a journal which had been so adamant about the integration of science into society, such a shift in policy could only have been made under the greatest duress. The change was itself primarily occasioned by Gregory's perception of scientists' experience under Hitler. Yet over a longer period of time some alteration in the leaders would have been necessitated had the journal's failure to resolve conflicting social and professional demands persisted.

A resolution of these difficulties was provided, however, two weeks after the signing of the Munich agreement over Czechoslovakia in an anonymous leader entitled "Science and National Service"[51]. It is of great significance that this article was written not by Gregory or Brightman but by the young crystallographer and Marxist philosopher, J. D. Bernal. In the year preceding Munich, Bernal had worked vigorously on both the International Peace Campaign and his forthcoming book, *The Social Function of Science*[52]. He was then persuaded by his friend Solly (now Sir Solly) Zuckerman, in September 1938, that the likelihood of war demanded a careful analysis of the ways in which scientists could best be used by (and/or protected from) the government (S. Zuckerman, personal communication). Gregory, as has already been demonstrated, was vexed by the same situation and therefore welcomed the first fruits of Bernal's work in this area. The latter's first concern was that any mobilization of science for self-defence would not be satisfactory ". . . unless its ultimate aim—the utilization of science for human welfare in times of peace—is kept steadily in view. . . . Consequently, the organization of scientific workers for war must be conceived in such a way that the minimum damage is done to the possible beneficial utilization of science. This involves the safeguarding of fundamental scientific research and of the main lines of its application, so that once the danger of war is definitely removed, science can advance as rapidly as possible in carrying out its true purpose"[51].

Bernal further specified that scientists could not be expected to support either a plan prepared by civil servants or a war directed "against the principles of democracy and civilization"[51]. Having defined the conditions under which researchers would participate, he next attacked the ways in which science was then organized. "Preparation for . . . war requires not only a much more thorough organization of science, but also a much closer integration between scientific research and other activities of the community, particularly those of industrial production, agriculture and health"[51]. In fact, "We need a National Research Council covering the whole of science and relating it to the running of the community *both in peace and in war*". Such a body would be responsible for, first, the determination and, second, the allocation of scientific resources. Bernal envisaged the principal tasks for science in wartime to be: the maintenance of military and civil populations, as well as of war production; defence against aerial attack; assistance in the planning of military operations; and care of casualties. As a means to these ends he recommended an immediate intensification of both fundamental and applied research related to food, non-ferrous metals, rubber, motor fuel, optical instruments and medical supplies. Apart from the utility of their investigations, Bernal finally emphasized the general contributions which the scientists' quantitative and critical outlook could make to the successful conduct of war. "The full utilization of scientific workers requires the use of their ingenuity far more than of their routine service, and this can only be secured by giving them opportunities and liberty of initiative"[52].

The significance of Bernal's leader for the development of *Nature*'s concept of a national science policy cannot be stressed too much[53]. While his article reaffirmed the desirability and practicability of a socially orientated plan for scientific activities, it also attempted to conserve important professional values. Yet the context in which Bernal and *Nature* chose to defend such traditional ideals could not but alter their meaning. For example, the journal had tended up until 1938 to identify the scientific outlook with pacifism. Now it was socially responsible for a researcher to lend his talents to the military defeat of any nation which attempted to abrogate both the freedom of its own scientists and the internationalism of the scientific community. By the same token, scientists who placed the service of an undemocratic state ahead of their devotion to truth were to be ostracized from science's international brotherhood. Finally, unlimited freedom of research might be curtailed when society in a time of economic or military crisis called for the assistance of limited scientific resources. Such values as the internationalism, freedom, and social responsibility of scientists could not, in short, be upheld both universally and simultaneously. Once science was consciously placed in a specific social context, a conflict between such concepts became all the more likely. The following problem therefore emerged: if one value had to be subordinated to another, who would make such a decision and on what grounds? A satisfactory answer to that question has eluded contemporary philosophers of science, no less than it did Sir Richard Gregory's *Nature*.

I am grateful to the present staff of *Nature* for their assistance in this research on their predecessors.

Proposed Mechanism of Force Generation in Striated Muscle

A. F. HUXLEY & R. M. SIMMONS
Department of Physiology, University College London, Gower Street, London WC1

Recordings of the change in tension in striated muscle after a sudden alteration of the length have made it possible to suggest how the force between the thick and thin muscle filaments may be generated.

ONE approach to the elucidation of the kinetics of movement of the "cross-bridges" which are widely assumed to generate the relative force between the thick and thin filaments during contraction of a striated muscle fibre is to record and analyse the transient response of stimulated muscle to a sudden change either of tension or of length. Considerable progress has been made in this way by Podolsky and his colleagues[1-3] who recorded the time course of shortening after a sudden reduction in load. Similar responses have been recorded repeatedly in this laboratory but have not been published because we did not succeed in making the tension change sharply enough to distinguish the component of length change that is truly synchronous with the tension change from that which lags behind the tension change. We therefore turned[4] to the inverse type of experiment, in which the length of the fibre is suddenly altered (by ±0.1–1.5%) and the time course of the resulting tension change is recorded. The results have led to some fairly definite suggestions about the way in which the cross-bridges may actually produce the force between the thick and thin filaments.

All the experiments were carried out on isolated fibres from the semitendinosus muscle of the frog *Rana temporaria*, at 0°–4° C. Length changes, complete in less than 1 ms, were produced by means of a servo system[5], and tension was recorded with a capacitance gauge[6]. Compliance in the apparatus itself is small enough to be completely disregarded; precautions were taken to reduce the compliance in the tendon attachments to a minimum, and in some of the experiments it was eliminated altogether by using the "spot-follower" device[5], which continuously measures the length of a middle segment of the fibre.

Responses to Stepwise Length Change

The general time course of tension in these experiments is shown in Fig. 1. This article is concerned only with the changes that occur simultaneously with the length change itself and during the first few milliseconds after it. As has already been briefly reported[4], these changes are of the kind shown in Fig. 2: the tension undergoes a relatively large alteration simultaneously with the step change of length, but recovers quickly towards a level closer to that which existed before the step. The final recovery to the original tension which has been seen by many earlier investigators[7-9] takes place on an altogether slower time scale. The early changes seen in Fig. 2 have only come to light through the improved time resolution of present-day apparatus.

The behaviour shown in Fig. 2 suggests the presence of two structural elements in series. One of these would be an elastic element whose length is altered simultaneously with the change of length that is applied to the whole fibre, thus producing the large initial change of tension. The other would be an element with viscous as well as elastic properties, whose length readjusts itself during the period of a few milliseconds immediately after the length change, as a result of the change in tension. As this readjustment proceeds, the imposed length change comes to be shared between the two structures, giving a tension intermediate between the values immediately before and immediately after the length change. At the time of our first note[4] about this quick initial tension recovery, we thought it likely that the recovery took place by sliding, with movement of the cross-bridges, but that the instantaneous elasticity was mostly in the filaments themselves. Since then we have measured these responses in fibres stretched so as to reduce the amount of overlap between thick and thin filaments. We found[10] that the responses to a given absolute length change were altered only by a reduction in the scale of the tension changes, which varied in direct proportion to the amount of overlap and therefore also to the number of cross-bridges capable of contributing to tension. On these grounds we now believe that the instantaneous elasticity (or at least the greater part of it) resides in the cross-bridges themselves, as well as the structure responsible for the tension recovery.

The relations between length change and tension are illustrated in Fig. 3. The curve T_1 shows the extreme tension reached during the step change of length. It is somewhat non-linear, becoming stiffer with increasing tension as is commonly found in biological materials. This curve is the best experimental approach that we have to the instantaneous elasticity of the fibre, but it is clear from records such as viii–x in Fig. 2 that the tension drop in the larger shortening steps is cut down because the quick recovery has progressed

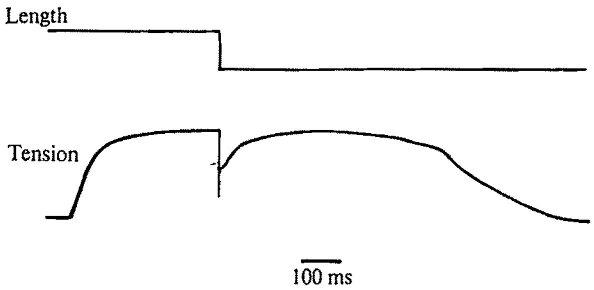

Fig. 1 Isometric tetanus of an isolated muscle fibre (frog, 4° C), with an imposed shortening step. This article is concerned with the tension changes during, and in the first few milliseconds after, the length step; these are shown on a fast time scale in Fig. 2.

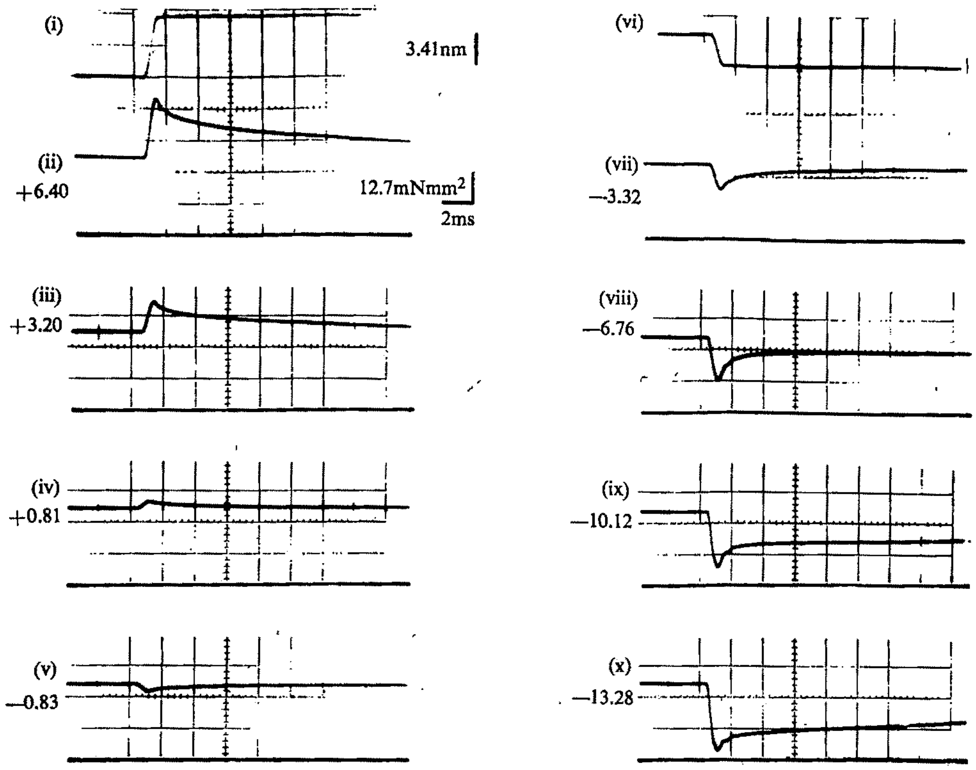

Fig. 2 Transient changes in tension exerted by stimulated muscle fibre when suddenly stretched (ii–iv) or shortened (v, vii–x); same experiment as Fig. 1, which shows the whole of the contraction during which record ix was taken. (i) and (vi): records of length change during tension records (ii) and (vii) respectively. The number by each tension record shows the amount of the length change per half-sarcomere, in nm.

to an appreciable extent before the length change is complete. The true curve of the instantaneous elasticity is therefore less curved on the shortening side than the curve of T_1 in Fig. 3; it is even possible that it is practically straight, as indicated by the broken line.

In contrast to this straightforward behaviour of the instantaneous elasticity, the quick tension recovery is highly nonlinear both in its extent and in its speed. The line T_2 in Fig. 3 shows the level approached at the end of the quick phase of recovery; for moderate amounts of shortening it has the unusual feature of being concave downwards, reflecting the fact that after a small length step the tension returns practically to its previous level (Fig. 2, iv, v). As regards the time course, it is evident from Fig. 2 that the early tension recovery is much more rapid in releases than in stretches, and that its speed varies continuously over a wide range with the size of the length step. The recovery is not exponential, but an estimate of the dominant rate constant can be obtained and is plotted against the size of the stretch or release in Fig. 4; it is roughly fitted by a curve of the form

$$r=\frac{r_0}{2}(1+\exp-\alpha y) \qquad (1)$$

All these features can be given at least a qualitative explanation if we assume that the force on a cross-bridge influences the length changes in that cross-bridge in the way that is assumed by Eyring and others[11,12] in their theory of the visco-elastic behaviour of high molecular weight polymers. The treatment presented in the following paragraphs is meant only to indicate the way in which these features would emerge from such a theory; a more complete treatment will be needed in order to test whether it is fully consistent with the data.

Assumptions

The key assumptions that have to be made are (1) that the movement by which a cross-bridge performs work during the period while it is attached takes place in a small number of steps, from one to the next of a series of stable positions with progressively lower potential energy, and (2) that there is a virtually instantaneous elasticity within each cross-bridge allowing it to shift from one of these stable positions to the next without a simultaneous displacement of the whole thick and thin filaments relative to one another.

These assumptions could be incorporated into some of the mechanisms that have been proposed for the action of the cross-bridges, for example, that of Davies[13], in which each cross-bridge shortens by folding at a number of points, or that of H. E. Huxley[14], in which the head of the myosin molecule (*H*, Fig. 5) rotates relative to the thin filament, acting as a lever which pulls the thick filament along by a link *AB* which is also part of the myosin molecule. Our assumptions fit very conveniently on to H. E. Huxley's proposals, and we shall discuss them on this basis in the way illustrated in Fig. 5. The features shown there which are additional to H. E.

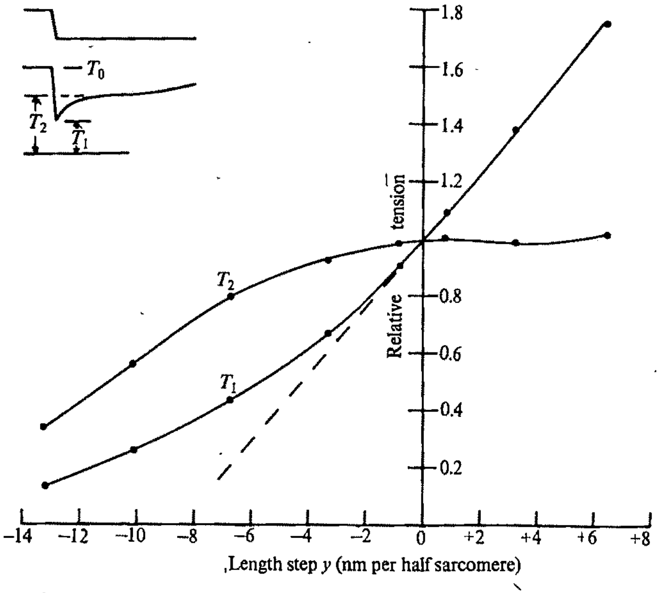

Fig. 3 T_1, Extreme tension reached during step, and T_2, tension approached during quick recovery phase, plotted against amount of sudden stretch (positive) or release (negative). Broken line: extrapolation of the part of the T_1 curve which refers to stretches and small releases. From records in Fig. 2.

Huxley's scheme are as follows. (1) The link *AB* is not inextensible as in H. E. Huxley's proposal but contains the instantaneous elasticity which shows up as curve T_1 (Fig. 3). (2) The head has a small number *s* of combining sites (M_1, M_2 and so on, in Fig. 5), each of which is capable of combining reversibly with a corresponding site (A_1, A_2 and so on) on an actin molecule in the thin filament. A single *M–A* attachment allows variation of θ (rotation in the plane of the diagram of Fig. 5) without hindrance, but no other degree of freedom of the myosin head relative to the actin molecule. (3) The affinity between these myosin and actin sites is smallest for M_1A_1, larger for M_2A_2 and so on. (4) The sites are placed so that the myosin head has $(s-1)$ stable positions, each of which allows two consecutive *M* and *A* sites to be attached simultaneously. (5) When the myosin head is in its $(s-1)$th stable position it can be detached from the thin filament by a process involving the hydrolysis of ATP.

On this basis the quick tension recovery is due to the tendency for the myosin head to rotate to positions of lower potential energy, while the fact that the recovery occurs at a finite speed is a manifestation of the rate constant for movement of the system from one of the stable positions to the next.

Potential Energy Diagram of a Cross-bridge

Curves i–iv in Fig. 6 show the potential energy diagrams for individual attachment sites (M_1A_1, M_2A_2 and so on) on a single cross-bridge. Each contains a flat-bottomed well extending over the range of myosin head positions where that particular attachment can exist. Curve v is the sum of curves i–iv, and therefore gives the total potential energy of the cross-bridge (in the absence of force in the link *AB*); it consists of a series of steps, separated by narrow troughs at the positions where two of the links are attached simultaneously. The depth of each trough will depend on the shapes, and on the exact positions, of the sides of the potential wells that contribute to it; it is assumed in Fig. 6 that these are such that the quantities E_1 and E_2 (v, Fig. 6) are the same for each of the troughs.

The total potential energy of an attached cross-bridge contains also the potential energy of stretching the elastic link *AB*. The latter term is shown in curve vi, and the total in curve vii.

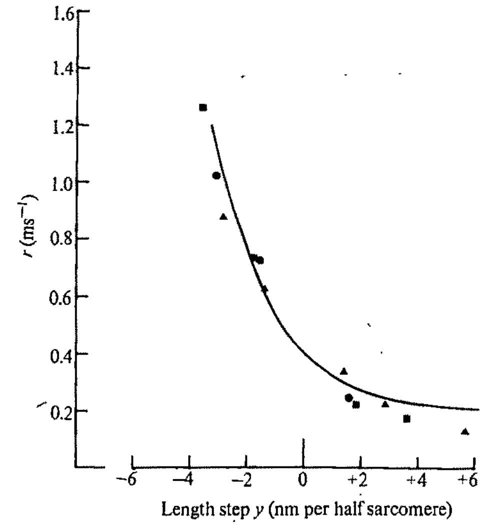

Fig. 4 Rate constant *r* of quick recovery phase following a length step of magnitude *y* (positive for stretch). Estimated as $(\ln 3)/t_{1/3}$ where $t_{1/3}$ is the time for recovery from T_1 to $(2T_2+T_1)/3$ (see Fig. 3). From three experiments using the "spot-follower" device; temperature 4° C. The curve is $r=0.2\ (1+\exp -0.5\ y)$.

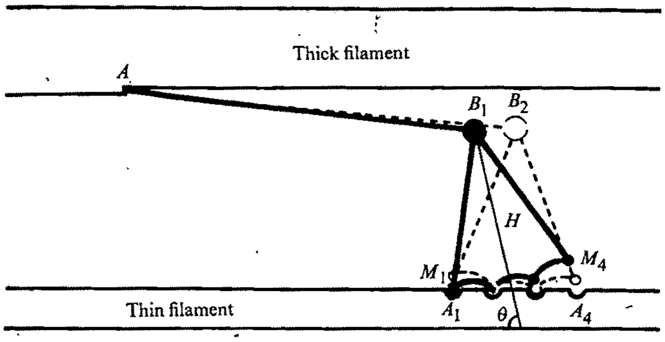

Fig. 5 Diagram showing assumed cross-bridge properties. The myosin head *H* is connected to the thick filament by a link *AB* containing the undamped elasticity which shows up as T_1 (Fig. 3) in the whole fibre. Full line shows head in position where M_1A_1 and M_2A_2 attachments are made; broken lines show position where M_2A_2 and M_3A_3 attachments are made.

Responses Expected Theoretically

In the mathematical section at the end of this article, we derive equations describing the response of a system of this kind to a step change of length. The system treated there is simplified by assuming that only two stable positions are available to each attached cross-bridge. The corresponding potential energy diagram is sketched in Fig. 7. This shows that B_2, the activation energy for transfer of a bridge from position 1 to position 2, contains a term *W* which depends on the force in the link *AB*, being increased by a stretch and reduced by a release. B_1, however, the activation energy for the reverse transfer, contains no such term and is independent of the force. It is this asymmetry which enables the theory to account for the way in which the rate constant of the quick tension recovery varies with the direction and magnitude of the length step: the theoretical result is expressed in equation (12) which is identical in form with equation (1), already shown (Fig. 4) to represent adequately the experimental data. The theory also leads to equation (16) for the tension level approached at the end of the quick recovery phase; this is plotted in Fig. 8 which is seen to reproduce the main features of the experimental T_2 curve in Fig. 3.

The two striking features of the quick tension recovery are thus accounted for by this theory. The numerical values used in obtaining this degree of agreement are: E_1-E_2, the potential energy difference between the stable positions of attachment of a cross-bridge, is equal to 4 kT; *h*, the travel of point *B* between its two stable positions, is 8 nm; *K*, the stiffness of the link *AB*, is 2.5×10^{-4} N m^{-1}.

The following considerations show, however, that the assumption that the cross-bridge movement takes place in a single step is probably not correct.

Isometric force and number of bridges. Equations (4) and (7) show that the isometric force per attached cross-bridge is $(E_1-E_2)/h$; with the values mentioned in the last section this amounts to 2.0×10^{-12} N. To reach a total force of 3×10^5 N m^{-2}, such as real fibres produce, would therefore need 1.5×10^{17} attached bridges m^{-2} in each half-sarcomere. This is about 1.5 times greater than the number of myosin molecules present. The discrepancy would be greater if the number of cross-bridges were equal to the number of projections on the thick filaments detected by low-angle X-ray diffraction since this appears to be about half the number of myosin molecules[15], and greater still if a substantial proportion of the cross-bridges were unattached during isometric contraction. (It is conceivable that each of the two heads on a myosin molecule should be counted separately; this would be appropriate only if the instantaneous elasticity existed within each of the heads, allowing them to shift independently.)

Work per attached cross-bridge. An upper limit to the external work done by the fibre per cross-bridge attachment will be given by the integral in equation (17), between the

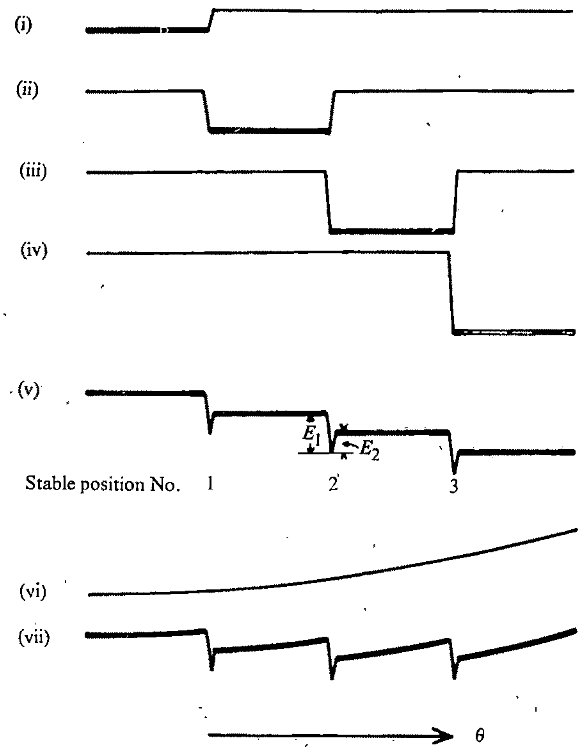

Fig. 6 Potential diagrams relating to the system illustrated in Fig. 5. i–iv, Diagrams for individual attachments M_1A_1, M_2A_2, M_3A_3, M_4A_4 respectively; in each the thick line corresponds to the range of θ within which the corresponding M and A sites are attached; v, sum of i–iv, giving potential energy of a system composed only of a myosin head and a thin filament; vi, potential energy due to stretching the elastic link AB; vii, total potential energy.

isometric point $y=0$ and the point ($y=-12.0$ nm) where $\varphi_2=0$. With the adopted values of α and h, this is 3.8 kT. This result is only about half the value which can be calculated as follows from the actual performance of frog muscle. Work can be as much as 40% of (work+initial heat)[16], and the latter quantity is about 11 kcalories/mol^{-1} of phosphorylcreatine split[17], giving the work term as 4.4 kcalories/mol.$^{-1}$. This is equal to 7.3 kT per molecule, which will represent the work per cycle of attachment and detachment of a cross-bridge if it is assumed that the cycle is coupled (presumably through ATP) to the hydrolysis of one molecule of phosphorylcreatine.

Probable number of stable positions. The quantitative treatment just presented has thus led to low values for the force and work per cross-bridge. It is just possible that revised values for α and for the number of cross-bridges will resolve these discrepancies, but it seems to us more likely that it will be necessary to assume that the cross-bridge movement takes place not in a single step but in two or perhaps more. This would lead to proportional increases in the calculated force and work, but the expected time course and extent of the quick tension recovery, which are already in good agreement with the experimental results, would not be much altered if each step has the same height E_1-E_2 as has already been assumed and the value of h is reduced so as to keep the same total range of travel. Fig. 5 is drawn for the case where the number of steps is 2 (3 stable positions and 4 points of attachment), which at present seems the most probable number.

Relation to Earlier Theories

The idea of applying Eyring's theory of polymers to muscle is not new. A comprehensive theory of muscle was developed by Polissar[18], in which the shortening of links in actomyosin chains was influenced in this way by the load, but this theory lost its relevance when it became clear that major changes of length take place by sliding, not folding, of the filaments.

The proposal that the sliding movement is generated by the tendency of attachments between the filaments to move through a series of a few positions of progressively lower potential energy was made many years ago by H. H. Weber[19], who also pointed out that in this case the rate constants for shifting from one position to another would be affected by the force on the attachment. He discussed this idea purely on the basis of a translational movement of the thick relative to the thin filament, with a site rigidly fixed to one of the filaments transferring itself from one to the next of the sites on the other filament to which it could be attached. It is difficult to visualize a mechanism of this kind operating over the rather large distances—several nanometres—that the transient responses show to be involved, but the difficulty disappears if there is an elastic structure allowing one of the attachment sites to undergo substantial displacements relative to the filament to which it belongs.

On the kinetic side, the scheme discussed here combines the advantages of the proposals made by A. F. Huxley[20] in 1957 and by Podolsky *et al.*[3]. In each of these schemes the production of force was assumed to occur as an immediate consequence of the formation of a myosin–actin link. In A. F. Huxley's scheme, attachment was assumed to be the main rate-limiting factor in steady shortening, while detachment after the performance of work by a cross-bridge was relatively rapid; with these assumptions it is possible to fit A. V. Hill's relations between load, speed and heat production but not the transient responses discussed here. Podolsky *et al.* reversed the assumptions about the rate constants, making attachment rapid and breakage rate-limiting; in this way they were able to fit many aspects of transient responses but, as they recognized, not the thermal data. With appropriate rate constants for the initial attachment and final detachment of each cross-bridge, the present scheme can probably account for the force–velocity and thermal relationships in the same way as A. F. Huxley's 1957 scheme, while the rapid transfer between stable positions of the myosin head produces transient responses not unlike those which, on the theory of Podolsky *et al.*, result from the rapid formation of new attachments. The present proposal is able to combine the successful aspects of both of these theories because it subdivides the force-generating event into distinct stages, one for attachment and others for stretching the cross-bridge, the latter being much more rapid than the former. This separation also removes another difficulty that both of the earlier theories would very likely have met in a fully quantitative treatment. They assumed that tension is already present in the cross-bridge when it attaches to the thin filament; thermal motion would so seldom bring the cross-bridge to such a large deflexion that it might be impossible to account in that way for the rapidity of contraction that some real muscles achieve.

Mathematical Section

Equations will be derived for the extent and time-course of the quick tension recovery to be expected from a system

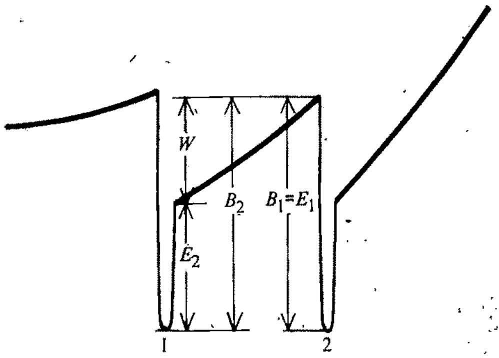

Fig. 7 Potential energy diagram equivalent to Fig. 6 (vii) but referring to the simplified system with only two stable positions.

similar to that shown in Fig. 5 but with only two instead of three stable positions of the myosin head relative to the thin filament. The following additional simplifying assumptions are also made. (1) Actual detachment and re-attachment of cross-bridges are slow enough to be disregarded. (2) Filaments themselves are completely rigid. (3) Filaments undergo no sliding movements except when the total length of the fibre is being altered. (4) The elasticity of the link *AB* obeys Hooke's law. (5) The link *AB* is capable of exerting negative as well as positive tensions. (6) In the isometric steady state, every attached cross-bridge spends equal amounts of time in each of the two available positions (this cannot be strictly true in real muscle because the spacings along the thick and thin filaments are not in any simple ratio, so the relative positions of the myosin and actin molecules must vary from one cross-bridge to another). (7) The time taken in transferring from one to the other of the two positions is negligible.

The following notation will be used; n_1: fraction of attached bridges in position 1; n_2 $(=1-n_1)$: fraction of attached bridges in position 2; y: displacement of thick relative to thin filament when fibre is stretched or shortened (zero in isometric state before the applied length change; positive for stretch); y_0: extension of elastic link *AB* when bridge is midway between positions 1 and 2 (equal to amount of sudden sliding movement needed to bring tension to zero from the isometric state); h: increase in length of *AB* when bridge shifts from position 1 to position 2; K: stiffness of link *AB* (assumed to obey Hooke's law); F_1: tension in *AB* when bridge is in position 1; F_2: tension in *AB* when bridge is in position 2; φ: time average of F_1 and F_2.

From these definitions,

$$F_1=K(y+y_0-h/2) \text{ and } F_2=K(y+y_0+h/2) \qquad (2)$$

and the time average of tension is

$$\begin{aligned}\varphi&=n_1F_1+n_2F_2\\&=K(y+y_0-h/2+hn_2)\end{aligned} \qquad (3)$$

In the isometric state, $y=0$ and $n_2=1/2$, and this equation reduces to the expression for the isometric force per attached cross-bridge

$$\varphi_0=Ky_0 \qquad (4)$$

The rate constants k_+ for transfer from position 1 to position 2, and k_- for transfer from 2 to 1, are governed by the energy barriers B_2 $(=E_2+W)$ and B_1 $(=E_1)$ respectively (Fig. 7). W is the work done in stretching *AB* when the bridge transfers from position 1 to position 2, and is given by

$$\begin{aligned}W&=h\,\frac{F_1+F_2}{2}\\&=Kh(y+y_0)\end{aligned} \qquad (5)$$

from equations (2).

Assuming the ks proportional to $\exp\,-B/kT$, we have

$$\begin{aligned}k_+&=k_-\exp\,(B_1-B_2)/kT\\&=k_-\exp\,(E_1-E_2-W)/kT\\&=k_-\exp\,(E_1-E_2-Kh(y+y_0))/kT\end{aligned} \qquad (6)$$

where k_- is constant since B_1 is a fixed quantity independent of the tension in *AB*.

In the isometric state we have assumed $n_1=n_2$, so $k_+=k_-$; also $y=0$ since y is defined as a length change from the isometric state. It then follows from (6) that

$$E_1-E_2=Khy_0 \qquad (7)$$

and (6) becomes

$$k_+=k_-\exp-y.Kh/kT \qquad (8)$$

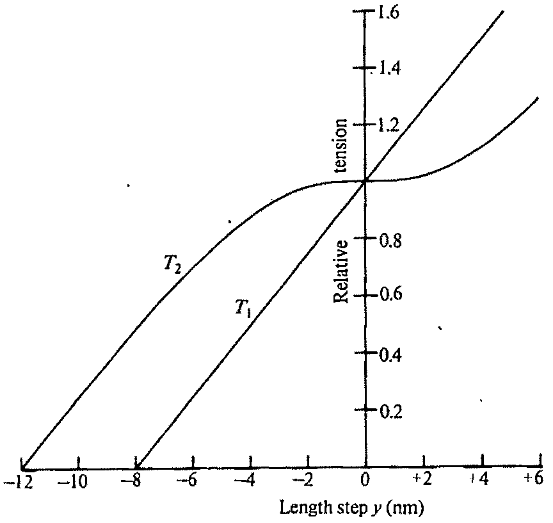

Fig. 8 Curves of T_1 and T_2 calculated from the simplified system, plotted on same scales as the experimental values in Fig. 3. T_2 curve: Equation (15) with $E_1-E_2=4\,kT$, $1/\alpha=2$ nm, $h=8$ nm.

In the experiments we are considering, y is suddenly altered by imposing a length change on the muscle fibre, and is subsequently held constant. The transfer of myosin heads from one position to the other is then governed by the equation

$$\begin{aligned}\mathrm{d}n_2/\mathrm{d}t&=k_+n_1-k_-n_2\\&=k_+-(k_++k_-)n_2\end{aligned} \qquad (9)$$

This equation represents an exponential approach, with rate constant r given by

$$r=k_++k_- \qquad (10)$$

towards an equilibrium where

$$n_2=k_+/(k_++k_-) \qquad (11)$$

Substituting from (8) into (10) we have

$$r=k_-(1+\exp-y.Kh/kT) \qquad (12)$$

This has the same form as equation (1), and the equations become identical, giving approximate agreement with the experimental results in Fig. 4, if we take

$$Kh=\alpha kT \qquad (13)$$

Equation (8) can therefore be written

$$k_+=k_-\exp-\alpha y \qquad (14)$$

and (11) becomes

$$n_2=\frac{1}{2}\left(1+\tanh\frac{\alpha y}{2}\right) \qquad (15)$$

The tension φ_2 at the end of the quick recovery (corresponding to T_2 in the whole fibre) is obtained by combining (3), (13) and (15) to give

$$\varphi_2=\frac{\alpha kT}{h}\left(y_0+y-\frac{h}{2}\tanh\frac{\alpha y}{2}\right) \qquad (16)$$

The work done during shortening at a low enough speed so that n_2 always has its equilibrium value would be obtained by integrating (16):

$$\int\varphi_2\mathrm{d}y=kT\left(\frac{\alpha y}{h}\left(y_0+\frac{y}{2}\right)-\ln\cosh\frac{\alpha y}{2}\right) \qquad (17)$$

To match the points in Fig. 4, α is taken as 5×10^8 m^{-1}, the value used for the curve in that figure. (E_1-E_2) is shown by equations (7) and (13) to be equal to $\alpha y_0 kT$. From Fig. 3 (broken line), y_0 is about 8 nm, giving $E_1-E_2=4\,kT$. h has to be chosen to give the right shape for the curve of T_2 against y (equation 15). A value $4/\alpha$, or 8 nm, is used in Fig. 8; lower values give a less inflected curve and higher values give a curve with a region of negative slope.

Generation of Tension

The tension changes observed in the first few milliseconds after suddenly changing the length of an active muscle fibre suggest the following mechanism for the generation of tension or shortening by the cross-bridges. Each cross-bridge has three stable positions with progressively lower potential energies, in steps of about 4 times kT, separated by about 4 nm of travel. Transfer from one of these positions to the next is made possible, without simultaneous displacement of the whole filaments through an equally large distance, by the presence of elasticity associated with each individual cross-bridge. The tension generated in this way in the elastic element will show up as such if the muscle length is held constant, or will help to make the filaments slide past each other if shortening is permitted.

A simplified theoretical treatment is given; a more complete treatment will be presented later.

How Dextrous was Neanderthal Man?

JONATHAN H. MUSGRAVE

Department of Anatomy, The Medical School, University Walk, Bristol BS8 1TD

Results of multivariate statistical analyses indicate that the bones of the hand of Neanderthal man were metrically and morphologically unique and that he may not have been as dextrous as living *Homo sapiens*.

THE postcranial skeleton of Neanderthal man has been studied less intensively than his skull. This is to be regretted because any serious attempt to re-assess the phylogenetic status of the Neanderthalers must be based on their total morphological pattern[1] and not solely on evidence of cranial variation. In an attempt to rectify this situation I have made a detailed study of as many as possible of the Neanderthal hand bones listed by Vallois and Movius[2]. Measurements were taken on these bones and on comparative samples of European Upper Palaeolithic, Mesolithic and modern hand bones. These measurements and indices calculated from them were then submitted to discriminant function (canonical variate) analyses and Mahalanobis's D^2 tests[3]. This article presents some of the conclusions drawn from this investigation[4].

Thumb

(1) The metacarpal seems to have been neither relatively nor absolutely short, as earlier workers had suggested[5,6], and it was instead the great transverse width of the head, a feature which had also aroused comment[7,8], which proved to be the most important dimension. This observation may be correlated with a very noticeable anatomical feature, a flange which runs up the distal half of the radial side of the shaft (Fig. 1). Into this was inserted opponens pollicis muscle, clearly large and powerful in Neanderthal man[9], a suggestion which is in keeping with recent theories on the role of this muscle as an abductor of the thumb in a firm grip[10]. Associated with this flange is a marked depression[8] diagonally opposite, from which arose the first metacarpal head of the first dorsal interosseous, another "power" muscle.

Other unusual features of the Neanderthal thumb metacarpal include an asymmetry in the transverse curvature of the head and the presence in several specimens of a condyloid rather than a saddle-shaped proximal articular surface. The asymmetry has been noted in some non-human primate genera[11,12] and may reflect difficulties in opposing the thumb to the other digits. The condyloid articular surface, clearly visible in the specimen from La Chapelle-aux-Saints[5] but only partly developed in those from Kiik-Koba[9] and La Ferrassie

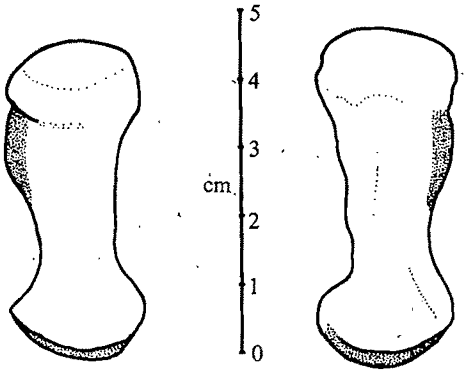

Fig. 1 Palmar aspect of Neanderthal thumb metacarpals. The principal features are: (1) the radially projecting ridge (stippled) into which was inserted opponens pollicis muscle; (2) the asymmetry of the curve of the distal articular surface; and (3) the narrow waist at the proximal end of the shaft, formed on the ulnar side by the impression for the origin of the first metacarpal head of the first dorsal interosseous muscle. Both specimens belonged to male Neanderthalers. Tracings were made from photographs of casts.

(La Ferrassie II, right), is also found in modern specimens[6]. The incidence of thumb metacarpals with atypical bases, however, seems rather high among the Neanderthalers and it will be interesting to watch whether future discoveries reveal a trend towards the development of this feature.

(2) The proximal phalanx is distinguished from its modern counterparts by its robusticity and especially its shortness. Discriminant functions show it to be significantly shorter than modern thumb proximal phalanges both absolutely and proportionately. For example, it is much shorter in proportion to the lengths of the other bones of the thumb than is a modern thumb proximal phalanx.

(3) The shortness of the thumb proximal phalanx is further highlighted by the great length of the distal phalanx. It was confirmed by *t*-tests that the Neanderthal sample was significantly longer, relative to the length of the other bones of the thumb and, of course, the whole thumb, than any of the samples analysed. That so many independent statistical analyses confirmed the shortness of the thumb proximal phalanx and the great length of the distal phalanx indicates that these are important features and ones which may have affected the range for grips used by Neanderthal man.

In addition to being very long the Neanderthal thumb distal phalanx is very broad transversely across its mid-shaft and head; these dimensions are also shown to be important by the discriminant functions (Fig. 2). It is not clear why all Neanderthal thumb distal phalanges, from France to the Crimea, should have broad distal tuberosities, but there are two possible explanations for this trait: first, a broad distal end would support a large distal pulp space, which might be useful in a powerful grip; second, a voluminous pulp space would also presumably be highly vascular, and hence useful in a cold climate.

As well as being broad the whole of the distal end of this bone in most Neanderthal specimens is markedly deflected to the medial side of the hand, a feature which is frequently noticed in modern specimens[13]. It is so noticeable and persistent in the Neanderthal thumbs, however, that it is tempting to postulate that it may be correlated with an imperfect development of efficient opposition. If the distal end is already tilted a millimetre or so to the index finger then such an arrangement, like the asymmetrical curve of the metacarpal head, might help to compensate for any pecularities in the shape of the carpometacarpal joint which might impede efficient opposition.

The shortness of the proximal phalanx and the length of the distal phalanx do not seem to have affected the total length of the only three complete Neanderthal thumbs measured—101.4 mm La Ferrassie I, left); 99.6 mm (La Ferrassie I, right); and 86.8 mm (La Ferrassie II, right). The means and standard deviations of this small sample are 95.9 mm and 8.0 respectively, which compare with scores of 94.2 mm and 7.6 for a sample of thirty-eight modern European thumbs. Furthermore, the thumb apparently was not very short in proportion to the lengths of the index and middle fingers as *t*-tests confirmed.

The chief characteristics of the Neanderthal thumb can be summarized as follows. It was a powerful digit of average length. The metacarpal was not short, but its head was asymmetrically curved and some of its intrinsic muscles, notably opponens pollicis and the first dorsal interosseous, were apparently extremely well developed. The proximal phalanx was exceptionally short and robust. The distal phalanx on the other hand was exceptionally long and wide and its distal end was tilted well over to the medial (or ulnar) side of the hand.

Index Finger

Separate canonical variate analyses of the metrical data on the index metacarpal and proximal phalanx support theories on the functional anatomy of this digit which previously had been based only on macroscopic examination of the bones themselves. Statistical analyses showed the metacarpal to be quite long, narrow transversely at the mid-shaft and extremely wide in the same plane at its head. Indeed, not only the thumb and index metacarpals but also metacarpals III, IV and V were found to have very wide heads. The index proximal phalanx was observed to be significantly shorter and wider across its base and mid-shaft than are the other samples of prehistoric and modern bones analysed.

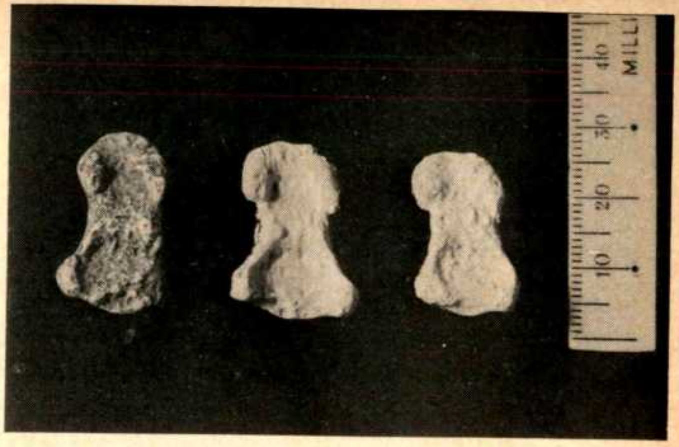

Fig. 2 Palmar aspect of casts of Neanderthal right thumb distal phalanges: (from left to right) La Ferrassie I; Krapina 203.1; Krapina 203.4. Note the stout distal tuberosities and the degree to which they are tilted away from the longitudinal axis of the shaft in an ulnar direction.

It is clear that the intrinsic muscles moving the index finger, especially the first dorsal interosseous, were extremely powerful. The evidence for this statement comes from the origins and insertion of this muscle. Its two bellies arise from the proximal half of the ulnar side of the shaft of the first metacarpal and from the whole of the radial side of the shaft of the second[14]. In the Neanderthal hand these areas of origin are clearly demarcated. First, the area on the first metacarpal, visible as a marked depression, has already been mentioned. Second, a sharp ridge or "crista dorsalis" may be seen running up the proximal one quarter of the shaft on the dorsum of at least four Neanderthal index metacarpals—La Ferrassie I, right; Spy 21A and 22A, right and left (Fig. 3); and Subalyuk, left[16]. This crest, by no means uncommon on modern specimens but frequently not so sharply defined, divides the second metacarpal bellies of the first and second dorsal interosseous muscles and only develops when these two bellies are large enough to warrant a bony separation from each other.

The two bellies of the first dorsal interosseous muscle unite to be inserted by a common tendon chiefly into the dorsal radial tubercle on the base of the index proximal phalanx[14,16–28]. This tubercle may be seen on all examples of this bone and is large enough to make the appearance of the whole of the base asymmetrical[24,29]. It is so large on the Neanderthal specimens that it expands the transverse diameter of the base until it equals almost half the length of the bone (Fig. 4). Moreover, this diameter, when expressed as a percentage of the length, was found to contribute most to the discrimination of the Neanderthal specimens from the others.

The possession of a very powerful first dorsal interosseous muscle presumably had a profound effect on the functional anatomy of the Neanderthal hand as a whole. The function of this muscle has never been determined precisely, but there is little doubt that its major role is that of abducting the index finger towards the thumb[19,20,30] and, by indirect action on the oblique lateral ligaments of the metacarpo-phalangeal joint, pronating the digit so that the distal palmar pad faces away from that of the thumb[24,29].

When a small object is held in a fine pulp-of-thumb to pulp-of-index finger precision grip, the index finger is adducted towards the little finger so that as much as possible of the pulp

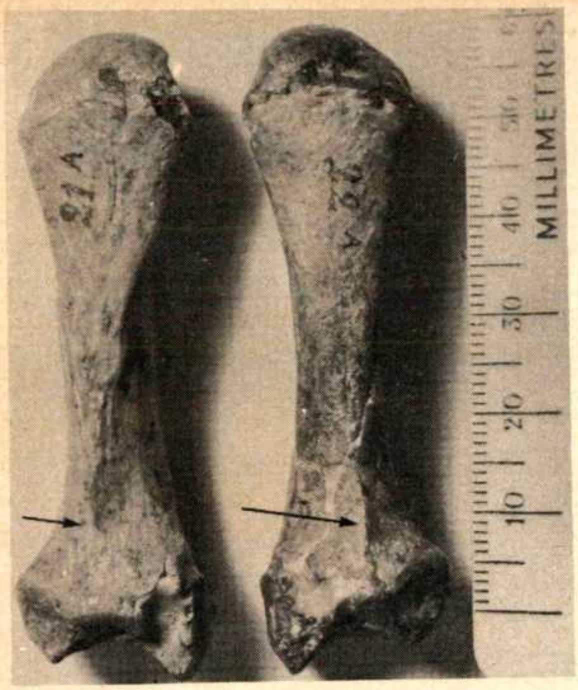

Fig. 3 Dorsal aspect of Neanderthal index metacarpals: Spy 21A (right) and 22A (left). Note the massive heads and bases and the well marked "crista dorsalis" (arrowed) running up the proximal one quarter of the shaft.

of the digit is supinated to oppose the pulp of the thumb. The first dorsal interosseous muscle is only active to prevent the index finger from being pushed too far towards the little finger should too much pressure be applied by the thumb. Precision and fine control may well be lost when this happens. It is suggested that the first dorsal interosseous muscle comes into its own, first, when the fingers are used as the other half of a powerful clamp with the thumb to anchor large spherical or cylindrical objects; and second, in a rather crude precision grip, the so called pinch grip or key grip[22,23,29]. In this grip an object is held between the pulp of the thumb and side of the flexed index finger, at, for example, the distal inter-phalangeal joint or along the side of the middle phalanx. When objects are held thus the contracted bellies of the first dorsal interosseous muscle can be palpated easily. It is also the precision grip habitually adopted by many short-thumbed non-human primates[31,32].

It is also very tempting to suggest that it might have been the kind of precision grip favoured by Neanderthal man. Neanderthal man, however, certainly cannot be called short-thumbed. The ratio of the length of his thumb to his index finger was apparently little different from ours. By using left and right hand bones of La Ferrassie I it was possible to build up a composite index finger and demonstrate that the Opposability Index (length of thumb/length of index finger × 100) was 64.4, a score very close to the figure of 65.4 obtained from a modern sample of thirty-eight (standard deviation 1.94).

It nevertheless may not be the proportion between the total lengths of thumb and index finger that is important but rather the proportions of the individual bones. The proximal phalanges of both these digits in the Neanderthal hand were distinctly shorter than their modern counterparts. This feature alone may well have determined which kind of precision grip he habitually used. It is clear that the proportions of the lengths of the individual bones of a modern human digit are constant, especially in the thumb and index finger, and they presumably affect dexterity. Unfortunately not enough work has been done on the modern hand to allow a precise inference as to what advantages or disadvantages this feature conferred on the Neanderthal hand.

The Rest of the Hand

The other bones of the Neanderthal hand all indicate independently that it was a squat, powerful appendage.

(1) The carpus possesses several interesting features. The tubercle on the trapezium and the hamulus on the hamate are very large and form a deep carpal tunnel for powerful extrinsic flexor tendons (see Fig. 5). The distal articular facet on the trapezium of at least one specimen (Kiik-Koba, left) is strange enough to attract comment[9]. The articular facet for the fifth metacarpal on the hamate of another (La Ferrassie II, right) shows that the little finger could be abducted far enough to increase the span of the hand quite considerably (see Fig. 5).

(2) Metacarpals III to V are relatively long and, like metacarpals I and II, have characteristically wide heads. They are rather narrow at the mid-shaft, however, and this may well have been advantageous; the combination of wide heads and narrow mid-shafts would increase the volume of the inter-metacarpal spaces and hence the volume of the interosseous muscles.

(3) Proximal phalanges III to V, like proximal phalanges I and II, are relatively short. They have thick, wide bases and are very wide at the mid-shaft, presumably to accommodate stout tendons for the extrinsic flexor muscles. The projection formulae of the condyles on the heads of the proximal phalanges of the most complete male Neanderthal hand (La Ferrassie I, left) should also be mentioned. They are so arranged that the ulnar condyles on proximal phalanges II and III project further distally than the radial ones, and the radial condyles project further distally on proximal phalanges IV and V (Fig. 6). This feature may be seen on modern proximal phalanges, but it is so pronounced in this specimen that it is tempting to regard it as additional evidence that the Neanderthal hand possessed a very wide span. From other work[33,34], it seems that the asymmetry of the condyles on proximal phalanges II to V may play quite an important part in divergence at the proximal inter-phalangeal joints of these fingers.

(4) Middle phalanges II to V are very difficult to identify accurately. A comparative analysis of a random sample of Neanderthal specimens showed them nevertheless to resemble most closely middle phalanges II and V of a modern sample. In other words, they are rather short and robust with wide bases and heads, in contrast to the Upper Palaeolithic specimens which are much longer and thinner.

(5) Distal phalanges II to V are among the most interesting bones of the Neanderthal hand. They are relatively long and resemble most closely distal phalanges III and IV of a modern

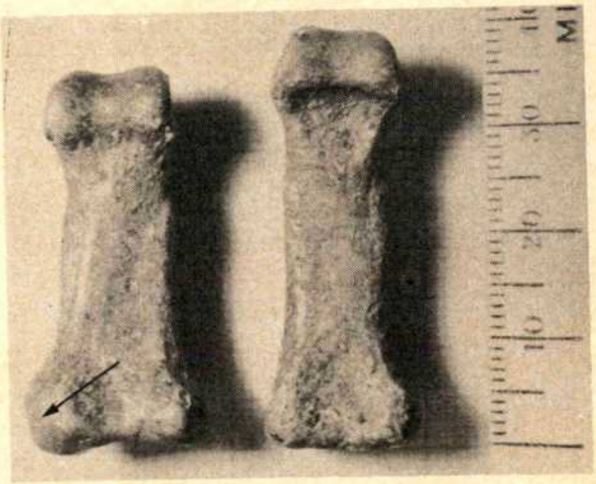

Fig. 4 Palmar aspect of Neanderthal index and ring proximal phalanges: Spy 24C (index; left) and 24A (ring; left). Note the massive development (arrowed) of the radial side of the base of the index proximal phalanx (24C).

sample. The bases and especially the heads are characteristically wide[9]. A possible explanation for this feature, observed on the distal phalanx of the thumb, has been proposed earlier.

This investigation thus seems to show that the Neanderthal hand possessed several distinctive metrical and morphological features. Each feature can be found in modern hands but they rarely occur combined in one individual hand. It seems therefore that the total morphological pattern of the Neanderthal hand was unique, a claim made more plausible by the complete lack of similarity between the hands of Neanderthal man and his immediate successor in time, Upper Palaeolithic *Homo sapiens* (that is, Cro-Magnon man). Whether these features reflect adaptations to his environment or imperfect development of manual skill is still not known. It is not unlikely that both these factors contributed something to the morphology of the Neanderthal hand.

I thank Dr J. R. Napier and Dr M. H. Day, my supervisors; Dr M. R. B. Clarke and his colleagues at the University of London Institute of Computer Science; and all the people who allowed me to study the fossil hand bones in their care. This project was financed by Churchill College, Cambridge; the Wenner-Gren Foundation for Anthropological Research, New York; the Boise Fund, University of Oxford; the Emslie Horniman Scholarship fund, Royal Anthropological Institutes; and the Dowager Countess Eleanor Peel Trust, Lancaster Royal Grammar School.

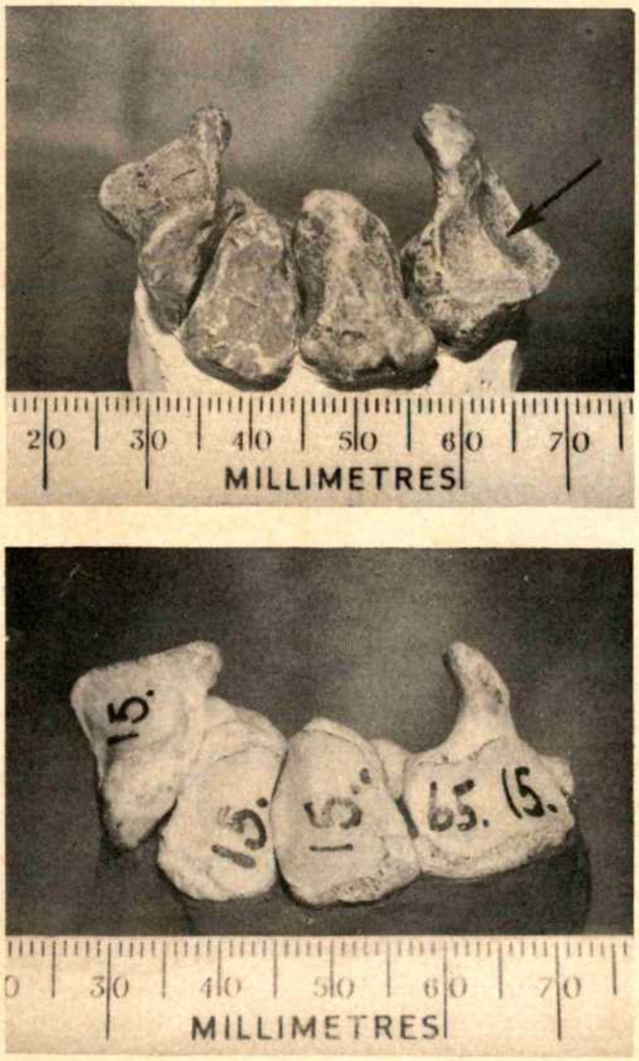

Fig. 5 Cast of the articulated carpus of the right hand of La Ferrassie II (female) compared with that of a modern Western European female (65.15). This view of the distal articular surfaces of the distal row of carpal bones shows the large tubercle on the trapezium and the large hamulus on the hamate features which increased the depth of the carpal tunnel. Note too the discrete and ulnar deviated facet (arrowed) for the fifth metacarpal on the hamate of La Ferrassie II.

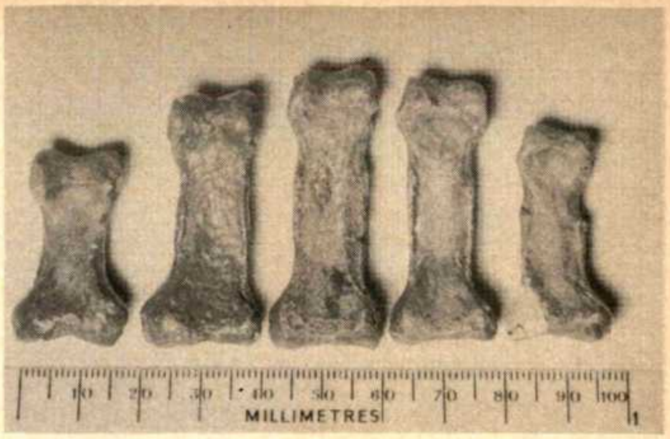

Fig. 6 Palmar aspect of, from left to right, casts of proximal phalanges I to V of the left hand of La Ferrassie I (male). Note the massive bases and heads, and the asymmetrical projection formulae of the condyles.

Deposition of Extraterrestrial Nickel in Marine Sediments

THE vertical distribution of nickel components in deep sea sediments was first obtained by the studies of long cores raised from the Swedish Deep Sea Expedition with the Albatros in 1947–1948[1]. The NiO content varied from a maximum of 0.089% by weight to a minimum of 0.041% by weight. Five distinct maxima occurred at various depths, and the average value was 0.056% by weight. Four sources of the nickel content in red clay were considered by Pettersson and Rotschi[1] and the extraterrestrial supply (meteoric dust) was considered by them as the most important. This interpretation of the origin of the nickel component, however, has received several objections[2–4].

Laevastu and Mellis[3] separated magnetic spherules from various depths in the same core, whose vertical nickel distribution has been studied by Pettersson and Rotschi[1]. In the article by Laevastu and Mellis[3] it is emphasized that no correlation between the spherule concentration and nickel content in the core was found.

Smales and Wiseman[2] and Smales, Mapper and Wood[4] have pointed out that the ratio of nickel to cobalt and nickel to copper in red clay is similar to the ratio in igneous rocks but very different from that in meteorites. In reference 3, nickel, cobalt and copper contents in igneous rocks, marine sediments and meteorites were determined using neutron activation analysis. Öpik has also discussed this problem[5] and he stated that comparisons of the ratio of nickel to cobalt are not important and the ratio of nickel to cobalt in solar atmosphere is closer to the ratio in red clay than that in meteorites.

In 1954 Goldberg[6] proposed an idea of the scavenging of various elements into the sediments by hydrated oxides of manganese and iron, and recently one of us proposed a simple model calculation of the nickel component in marine sediments[7].

The nickel component in marine sediments is considered to be supplied in two ways; grain settling and ionic (or colloidal) sedimentation. The former is independent of and the latter is dependent on the sedimentation rate. The expression is as follows:

$$\frac{a + bx}{\rho x} = C$$

where x (cm yr^{-1}) is the sedimentation rate of deep sea deposit, ρ = density of deep sea deposit, C (g of Ni per g of sediment) is the nickel content of deep sea deposit, a (g of Ni cm^{-2} yr^{-1}) assumed to be independent of time is the nickel sedimentation rate through grain settling and bx (g Ni cm^{-2} yr^{-1}) is the nickel sedimentation rate through ionic or colloidal sedimentation, in whose term it is expressed, that the ionic or colloidal sedimentation is related to x. A similar formulation to this was used by Barker and Anders[8] in the study of accretion rate of Ir and Os contents in deep sea sediments, but in that work no concept of grain and ionic supplies of the elements into marine sediments was expressed.

Table 1 Nickel Content in Lamont A 180–76

Zone	Interval (cm)	Duration (yr)	Sedimentation rate (cm per 10^3 yr)	Average nickel content (p.p.m.)
A	0–25	11,000	2.3	13
B	30–260	60,000	3.8	17
C	265–410	80,000	1.8	13

Table 2 Properties of Red Clay Core Lamont, V–20–130

Epoch	Palaeomagnetic event	Sedimentation rate (mm per 10^3 yr)	Average nickel content (p.p.m.)
1 Brunhes	Normal	0.76	104
2 Matsuyama	Reversed	2.47	102
3 Matsuyama	Normal	12.5	98
4 Matsuyama	Reversed	0.81	100
5 Matsuyama	Normal	3.4	84
6 Matsuyama	Reversed	0.47	77
7 Gauss	Normal	7.85	68
8 Gauss	Reversed	0.83	70

The settled grains are brought not only by extraterrestrial sources, but by continental and/or volcanic sources. The ionic and colloidal nickel fractions are of authigenic origin in seawater and they are obtained almost entirely from

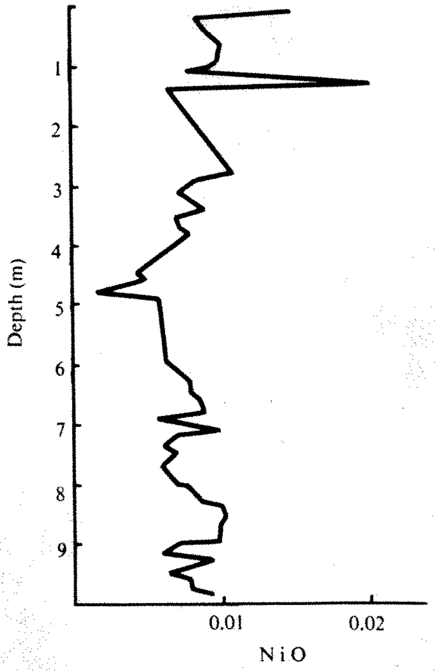

Fig. 1 The vertical distribution of NiO in V–20–130 core.

terrestrial sources. For this calculation the nickel content determination of dated cores is necessary but only two works have been published.

Turekian[9] determined nickel content in a calcareous core, Lamont A 180–76, which was dated using the radiocarbon method in 1958. The results are shown in Table 1.

The nickel concentration profile obtained by Amano, Okada and Shima[10] for a red clay core, Lamont V–20–130, is shown in Fig. 1. The same core was dated by Kobayashi using the palaeomagnetic dating method, which is shown in Fig. 2 (ref. 11).

From Figs. 1 and 2 one deduces the information shown in Table 2. The expression, $a+bx=\rho Cx$, is plotted in Fig. 3 using the data in Tables 1 and 2. The density used is 1.5 for a red clay core and 0.74 for a calcareous core. It can be seen from the figure that the coefficient of a is nearly zero. The parameters a and b are evaluated by a calculation of least squares as follows; $a=0.1\times10^{-6}$ (g Ni 10^3 cm^{-2} yr) and $b=121\times10^{-6}$ (g Ni cm^{-3}) for the red clay sample.

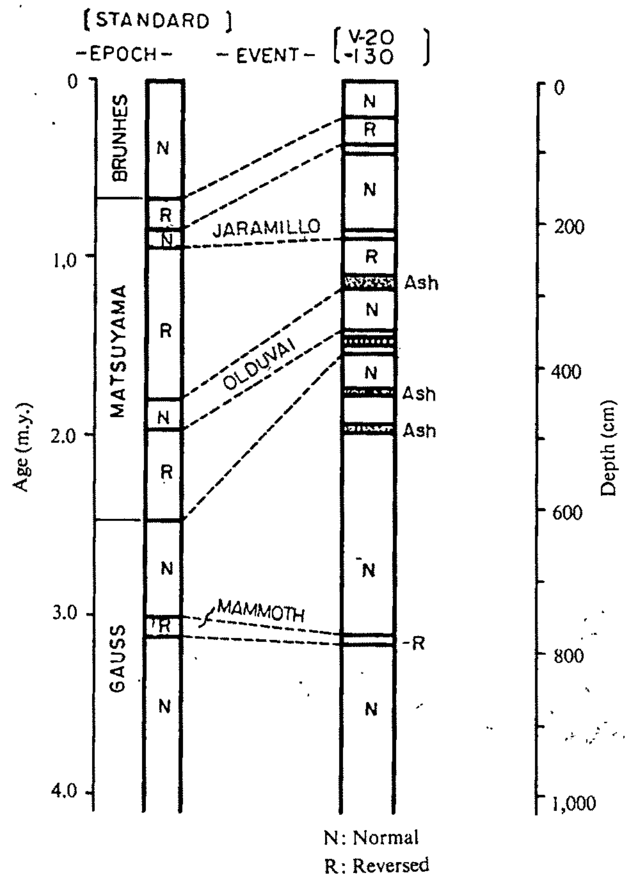

Fig. 2 Age determination of V–20–130 core using palaeomagnetic method.

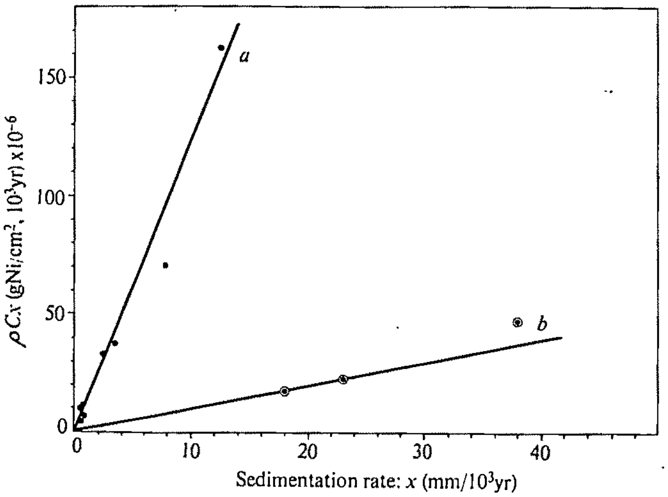

Fig. 3 Estimation of nickel fraction supplied through grain settling. $\rho Cx=a+bx$. a, Amano, Okada and Shima ($\rho=1.5$); b, Turekian ($\rho=0.74$).

Following Pettersson's hypothesis[1], a fairly large amount of nickel fraction is expected to be supplied through grain, that is meteoric dusts, into marine sediments.

We conclude that in marine sediments the nickel fraction supplied through grain settling is negligibly small, and that the extraterrestrial nickel fraction is supplied through magnetic spherules, whose concentration of ~1.1 mg kg^{-1} sediments was obtained by Laevastu and Mellis[3]. This does not reject the possibility of extraterrestrial dust accretion on the Earth, but the amount of the extraterrestrial fraction may be much smaller than Pettersson believed.

We thank Professor H. Hasegawa of the University of Kyoto for valuable advice.

Stratospheric Water Vapour Increase due to Human Activities

Great interest has been aroused by the possibility that a fleet of supersonic transports (SST) flying in the stratosphere would deposit sufficient water vapour to increase the average global concentration by about 7%, from 3 p.p.m. to 3.2 p.p.m. (ref. 1). The injection of this water vapour would result in a small decrease in stratospheric temperature according to Manabe and Wetherald[2,3]. Perhaps more significantly, it could decrease the concentration of ozone in the lower stratosphere through a series of photochemical reactions[4–9].

The consequences of this slight ozone reduction have been judged by some to be serious. (McDonald[10], for example, projects about 10,000 additional cases of skin cancer a year in the United States as a result of increased ultraviolet radiation due to a 1% reduction in total ozone content.) It is therefore of interest to see whether other human activities are increasing the water vapour content of the stratosphere. I believe that methane production[11–13] may be an important process today, perhaps more so than the hypothetical SST fleet of the future.

CH_4 is injected into the atmosphere mostly from the decomposition of organic matter at the Earth's surface, from swampy areas, rice paddies, geothermal areas, coal fields, natural gas and petroleum wells, and industrial centres. Koyama[14] has estimated some of the more important sources which contribute to the global atmosphere; the total production rate is about

Table 1 CH_4 Production Rates

	CH_4 g yr^{-1}
Paddy fields	1.4×10^{14}
Enteric fermentation of animals	4.5×10^{13}
Coal fields	2.0×10^{13}
Upland fields, grasslands and so on	1.0×10^{13}
Forests	4.0×10^{11}

2.7×10^{14} g yr^{-1}. They are shown in Table 1 which is by no means complete—for example, the methane production by swamps is probably as important as that of paddy fields[11] and there are no estimates for CH_4 production by various industrial activities and by the anaerobic digestion of sludges, sewage, and especially feedlot wastes. T. C. Byerly (private communication) has estimated the methane production from the metabolism of domesticated ruminants at 7.3×10^{13} g yr^{-1}, with wild ruminants adding another 10% to 50%. The growth rate for domesticated ruminants is estimated to be 1.5% yr^{-1} which seems low. Robinson and Robbins[15] have suggested a total production rate of 1.6×10^{15} g yr^{-1} or about 5 times that of Koyama.

The production of methane on a weight basis is roughly equivalent to that of higher molecular weight volatile organics, for example, terpenes and isoprene, for which the rate is estimated to be from 1.7×10^{8} tons yr^{-1} (ref. 15) to about 4.4×10^{8} tons yr^{-1} (ref. 16). Worldwide hydrocarbon emission is estimated at 0.9×10^{8} tons yr^{-1} and nearly half of this is in the form of gasoline and solvents[15]. The natural background concentration of methane in the atmosphere is estimated to average 0.93 mg m^{-3} (1.39 p.p.m.) over a Southern California mountain area during desert winds[17]; at Point Barrow, Alaska, the concentration is 1.1 mg m^{-3} (1.6 p.p.m., ref. 18) and between Washington, DC, and Puerto Rico the value is 0.83 mg m^{-3} (1.25 p.p.m., ref. 19). The methane content of ocean water is in equilibrium with that of the atmosphere[18,19] and the atmospheric average life of methane has been estimated to be from a few years[15] to twenty years[14].

The most significant fact for our purposes is that a large fraction, perhaps as much as 50%, of the methane production is "cultural", that is, related to human activities and—for want of a better index—related to the population and GNP; it is therefore growing at a rate of about 2% to 3% yr^{-1} (a doubling time of thirty years). The natural contribution in the meantime should remain constant or even decrease somewhat as swampy areas are filled in and as the wild ruminants are reduced in number.

Because of the low value in the atmosphere, approximately 1 p.p.m., the chief methane sink must be at the surface of the Earth, presumably in the form of aerobic bacteria[33–35]. Of special interest, however, is the rate at which methane is oxidized and converted into water vapour in the stratosphere. The data are sparse and are based on a few isolated balloon flights. Ehhalt[11] reports a reasonably constant CH_4 mixing ratio up to a height of 10 km, although the amount may vary on different days in different locations. Bainbridge and Heidt[20] report a constant mixing ratio up to about 17 km above East Texas followed by a rapid fall-off above the tropopause; the mixing ratio falls to 60% of the tropopause value at an altitude of about 23 km. Kyle *et al.* report a fall-off over New Mexico commencing at 12 km and reaching 20% of the earlier value at 22 km. (Care has to be exercised in interpreting this result, however. They refer to methane per air mass and use units of atm-cm; that is, units of reduced thickness. I have established by a personal discussion that their Fig. 3 plots the relative mixing ratio.)

From a rocket experiment Scholz *et al.* conclude that the methane is well mixed in the troposphere over New Mexico, but that it is consumed by chemical reactions within the stratosphere (ref. 22 and D. H. Ehhalt, private communication). They also estimate that methane oxidation in the stratosphere may contribute between 25% and 50% of the water vapour contained in the upper stratosphere. This conclusion is based on the observed methane concentration near the stratopause which is less than 0.05 p.p.m.v.

We can calculate the strength of the sink from the equation of diffusion and continuity

$$\Delta(\chi,\mathbf{v}) = -\delta\chi/\delta\tau + S \qquad (1)$$

where the left side expresses the three-dimensional gradient of the product of mixing ratio of a tracer and vector velocity; and the right side contains the partial derivative of concentration with time plus the source (or sink) S. When $\delta\chi/\delta\tau=0$ we find

$$S = K_{zz}\,[\delta\, n/\delta\, z - (\delta\, n/\delta\, z)_0] \qquad (2)$$

assuming only a vertical gradient in the z-direction K_{zz} is the eddy exchange coefficient ($\sim5\times10^{3}$ cm^2 s^{-1} at 50 mb), averaged over latitude and season (ref. 3 and ref. 23 in which the effects due to a mean vertical motion produced by the general atmospheric circulation are neglected). $\delta\, n/\delta\, z$ is the observed decrease in concentration of CH_4, $(\delta\, n/\delta\, z)_0$ is the expected decrease corresponding to a constant mixing ratio ($\sim2.75+10^{-16}$ g cm^{-4}).

Substituting numerical values from the two balloon experiments, we obtain $\delta\, n/\delta\, z\sim3.35\times10^{-16}$ and a rate of disappearance S of 3×10^{-13} g cm^{-2} s^{-1}. Over the Earth's surface this would be equivalent to about 44 million tons yr^{-1}.

Assuming that 1 g of CH_4 produces 2.25 g of H_2O after oxidation, we find that water vapour is introduced into the stratosphere by methane oxidation at the rate of 3.4×10^{6} g s^{-1} or about twice the rate of introduction by an SST fleet[24,25].

The straightforward interpretation of the observed rapid decrease in the methane mixing ratio, which begins at the tropopause, is that methane moves into the stratosphere from below, and is there chiefly oxidized into water vapour (this agrees with the conclusion of ref. 22 although exactly how much is oxidized, where and by what remains to be settled). A large fraction of the methane appears to be "cultural", so we conclude that the rate of injection of water vapour from methane produced by human-related activities today may be of the same order of magnitude as that injected by a fleet of supersonic transports (see Table 2).

Table 2 Water Vapour Injection into the Stratosphere

	g s^{-1}
By CH_4 oxidation *	3.4×10^{6}
Human-related portion †	1.7×10^{6}
Injected by SST fleet ‡	1.5×10^{6}
Injected by Hadley cell circulation §	5.0×10^{6}
Injected by thunderstorms ‖	0
Injected by tropical storms ‖	0

* Calculated in present paper.

† Estimated as 50% of *.

‡ 400 planes and 4 trips per day[24,25].

§ Calculated by Newell[26], but may be much greater. Newell uses a vertical velocity of 0.02 cm s^{-1} for the tropical tropopause. Higher velocities, up to 0.04 cm s^{-1}, are quoted by Lateef[31] and 0.05 cm s^{-1} is quoted by Reed and Vlcek[32]. A value of 7 to 10×10^{6} g s^{-1} is given by Newell in testimony before the Senate Appropriations Committee on March 10, 1971; his explicit neglect of middle latitude and thunderstorm sources is unacceptable because it is based on a circular argument.

‖ Firm estimates not yet available, but could be of the order of §.

The methane source has a more significant effect on the stratospheric ozone concentration than does the water vapour injected directly from the troposphere or from prospective SSTs. This is because atomic oxygen plays an important role in the oxidation of the methane[27], and is therefore removed and made unavailable for ozone production. These conclusions are not much affected by the detailed chemistry of the methane oxidation; as long as H atoms are conserved, the $H_2O : CH_4$ ratio is fixed. The water vapour produced will, of course, remove some ambient ozone[4–9] in the same way as the directly injected water vapour.

A more careful series of measurements of stratosphere methane concentration with altitude is required, especially at various latitudes, in order to determine the convective transport. It is important to note that nitrogen oxides and a large fraction of carbon monoxide are released into the atmosphere by human activities[28,29]. Leakage of these gases into the stratosphere would diminish ozone there by capture of atomic oxygen, and in the case of NO_x by direct reactions with ozone[30].

Mesozoic Palaeomagnetic Reversal Column

THE frequency of geomagnetic field reversals has not been constant throughout Phanerozoic time and there have been long intervals during which few, if any, reversals occurred; this is in contrast to the Tertiary, for example, when a reversal occurred, on average, every 0.23 m.y. in the interval[1] 0 to 10.6 m.y. The first long interval of fixed (reversed) polarity was discovered by Irving and Parry[2] and named by them the Kiaman Magnetic Interval. It extended from 290 until 230 m.y. ago approximately. More recently, Helsley and Steiner[3] have pointed out that the topmost of the lower and nearly all of the Upper Cretaceous was an interval of predominantly normal polarity (from about 120 until 70 m.y. BP).

McElhinny and Burek[4] have formally divided the Mesozoic period into (i) intervals of mixed polarity during which there were frequent reversals and (ii) intervals of predominantly normal polarity within which there are a number of reversed zones. They decided to name the intervals after people: thus their so called "Graham Interval" lasted from about 203 until 150 m.y. BP and their so called "Mercanton Interval" from about 120 until 70 m.y. ago. They also named the comparatively short "zones" of reversed polarity identified within these longer intervals of normal polarity.

Workers in the USSR have for many years specialized in the application of geomagnetic field reversals to stratigraphy. In particular, many of the zones described and named by McElhinny and Burek have already been named by a Russian palaeomagnetic researcher, D. M. Pecherski[5] in a paper entitled *Palaeomagnetism and Palaeomagnetic Correlation of Mesozoic Formations of North-east USSR*. This is included in volume 37 of the *Scientific Works of the North-East Complex Institute, Magadan*, entitled *Palaeomagnetic and Biostratigraphic Characteristics of some Important Mesozoic and Cenozoic Series from North and Far-East USSR*. At the fifteenth assembly of IUGG held in Moscow last August, Mr Pecherski agreed that a copy of his palaeomagnetic column for the Mesozoic be published in an English journal and Fig. 1 is a copy of Fig. 19 from ref. 5 with names translated into English by Pecherski himself. All (except one) of the reversed zones have been named after the locality in the USSR where they were recognized, although studies from other parts of the world have been taken into account.

The evidence for the division of the Mesozoic, from 203 to 70 m.y. BP, into three intervals by McElhinny and Burek is not so clear in the Pecherski column. If Pecherski's Kuldginskaja zone (Coniacian) is not the same as McElhinny and Burek's Akoh zone (Santonian), the Late Cretaceous normal interval contains at least three, rather than two, reversed zones and suggests that the recognition of three intervals within the Mesozoic may be an illusion. In this respect, it should also be noted that the representation of the so called Serra Geral zones by McElhinny and Burek is only schematic. Having worked on the Serra Geral lavas and dykes myself, I can say that at present we have no idea of how many reversals occurred during their emplacement (between about 145 and 110 m.y. BP). Pecherski recognizes three reversed zones in the time interval 137 to 120 m.y. BP (the Chagilskaja, Shirabadskaja and Severo-Sibirskaja). Between 150 and 137 m.y. the pattern is not clear (see Fig. 1).

On the whole, however, the agreement between Pecherski's column and that of McElhinny and Burek is rather good, but not exact. Thus the Akoh zone of McElhinny and Burek (at 80 m.y.) roughly corresponds to the Kuldginskaja zone of Pecherski (at 90 m.y.). The Hissar zone of McElhinny and Burek and the Gatanskaja zone of Pecherski both occur at 110 m.y. Within McElhinny and Burek's so called Graham interval of normal polarity, the Mateke and Cotswold zones correspond to Pecherski's Pospelovskaja and Startovaja zones and McElhinny and Burek's Nuanetsi zone corresponds to Pecherski's Maseru and Levo-Kedonskaja zones.

Pácherski has not recognized as many reversals within the Triassic as have been identified from studies of sedimentary columns in the Chinle and Chugwater formations from the USA and recorded in McElhinny and Burek's column. In other respects, however, Pecherski's column, based largely on studies of USSR rocks, appears the more complete. Nevertheless many reversals probably await discovery.

The radiometric time scale attached to the palaeontologically defined stratigraphic column used by Pecherski differs somewhat from the Geological Society Phanerozoic time scale[6] used by McElhinny and Burek. Measured K-Ar ages used by Pecherski are listed with their uncertainties in Fig. 1 in the column headed control and the time scale in the left hand column has been constructed using these measured ages.

The occurrence of these reversed zones within the predominantly normal Mesozoic has obvious potential uses in global stratigraphy. But whether the adoption of a new series of stratigraphic names is desirable or necessary is open to doubt. Could we not, for example, refer to the Gatanskaja (Hissar) zone as the reversed zone at 110 m.y. within the Late Cretaceous normal interval; and would it not be more constructive to refer to the Kuldginskaja zone as the reversed zone in the Coniacian division and to the Akoh zone as the reversed zone in the Santonian, and so on?

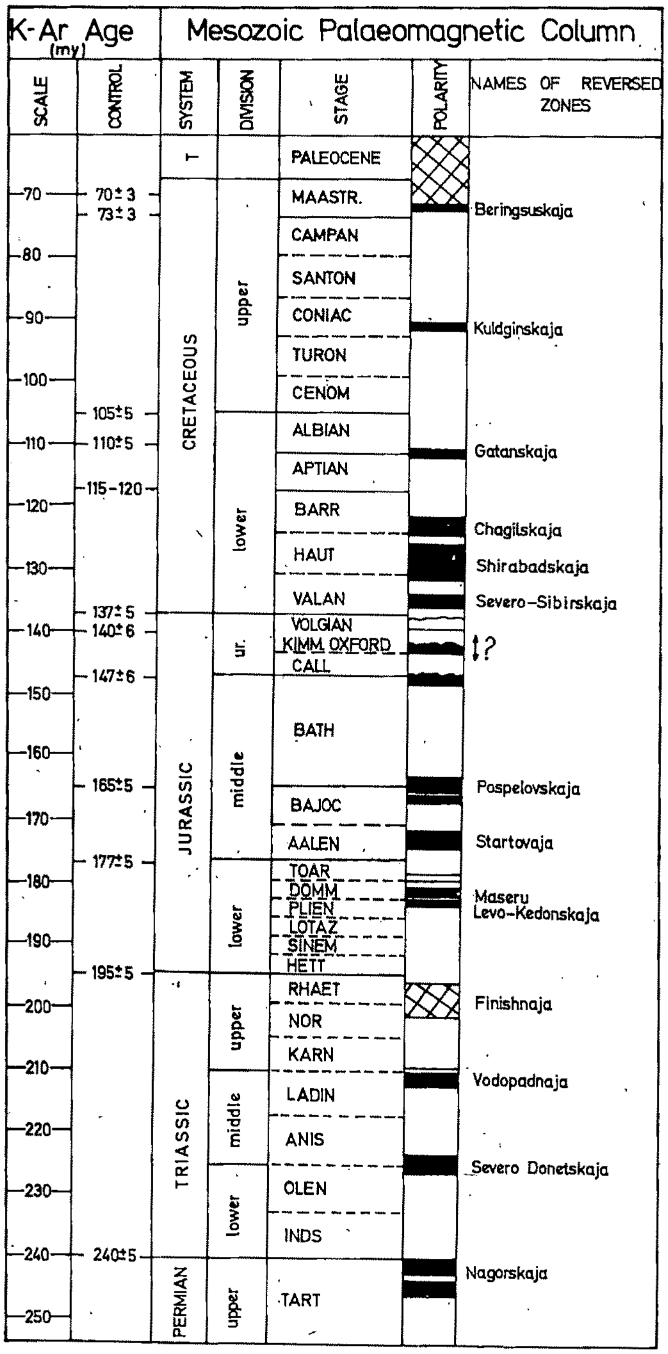

Fig. 1 Pecherski's Palaeomagnetic Polarity Column for the Mesozoic. Measured K-Ar ages are given in the column headed "control". The scale in the left hand column has been adjusted to the measured K-Ar ages. White areas, normal polarity; black areas, reversed polarity; hatched areas, times of frequent change in polarity of the geomagnetic field.

At present, however, we are faced with the problem that two sets of names have been assigned independently to the same set of observations. If we must use a new set of names to describe these zones, surely one set is quite sufficient. McElhinny and Burek describe how, a year or so ago, they each independently assigned different names to the same normal event within the Late Palaeozoic (Kiaman) reversed interval. McElhinny[6] named it the Oak Creek event and shortly afterwards Burek[7] named it the Graham event. These two authors resolved their difference by agreeing to adopt the earlier assigned name, Oak Creek.

Therefore, I venture to suggest that those who find a special set of names useful will recognize Pecherski's precedence by adopting his names to identify these Mesozoic reversed zones.

Recognition of Crude Oils by Capillary Gas Chromatography

In serious marine accidents involving oil pollution, the source of the oil is usually obvious, but on other occasions the offender often escapes undetected. In this communication, I propose a method of identifying the origin of spilled crude oil using capillary column gas chromatography.

Preliminary work with twenty-five fresh crude oils demonstrates that oils from different continents yield very different chromatograms, and that there are also significant differences between the chromatograms of oils from neighbouring fields in the Middle East and North Africa.

The three types of persistent oil likely to be spilled at sea are fuel oil, fresh crude oil and crude oil residues from tank cleaning; it is possible to differentiate between them by examining their wax and asphaltenes contents, and their volatility profiles as indicated by gas chromatography[1,2]. The technique described here could probably be applied to each of these oils to help trace its source, but it has so far been confined to crude oils.

Several techniques have been used to establish the origin of crude oils[1,3], of which the most useful are the determination of vanadium and nickel contents, the wax distribution, and "fingerprinting" by gas chromatography. This fingerprinting technique usually involves the use of packed columns to examine the higher boiling fractions, which are resistant to weathering by evaporation, but the fingerprints are limited in detail.

Experience gained in the identification of other petroleum products[4] suggested that average packed columns can provide sufficient compositional detail of materials up to carbon number

13 only, most of which would be lost by evaporation during weathering. It was envisaged that capillary columns would provide extra resolution and thus indicate compositional differences in the higher boiling fractions also.

As it is necessary to programme column temperatures to at least 300° C, the choice of stationary phase is virtually limited to the range of silicone gums such as 'SE-30'. But past experience of silicone gum capillary columns has been discouraging; resolution values of 10 could not be achieved with commercial or homemade 'SE-30' columns, whereas values of up to 40 could be obtained with squalane, for example.

(Resolution is measured between n-hexane and n-heptane and is defined as the distance between the peaks divided by their mean peak width at the baseline. The values quoted refer to columns 150 foot long by 0.01 inch internal diameter operated at 50° C and a nitrogen inlet pressure of about 10 pound inch^{-2}, adjusted to produce a retention time of 10 min for hexane.)

This unsatisfactory resolution is thought to be due to the nature of the gum which forms a skin on the surface of a solution, thus preventing the evaporation of the solvent beneath it; columns coated from solution by the usual techniques will not contain a stable, uniform film of stationary liquid.

Some new silicone stationary phases are viscous liquids rather than gums (which are almost solid at room temperature). We have found them to possess similar thermal stability to 'SE-30', by thermogravimetric analysis. Using 'OV-101' silicone (a non-polar variety) I have made columns providing resolution values of 40.

Table 1 Equipment and Operating Conditions

Chromatograph	Pye 'Model 54', fitted with homemade inlet splitter*.
Detector	Flame ionization.
Column	45 m of 0.25 mm internal diameter stainless steel tube coated with 'OV-101' silicone.
Temperature programme	50 to 310° C at 8° min^{-1}.
Carrier gas	Nitrogen.
Inlet pressure	10 p.s.i.g.
Column flow rate	Approximately 0.6 ml. min^{-1}.
Split ratio	100 : 1.
Injection temperature	300° C.

* This splitter was built to the outline design of Cramers[8] and is uniformly heated from the injection head to the split point to promote good vaporization of the sample.

I have so far examined fresh samples of crude oils from twenty-five different locations, using the equipment and operating conditions set out in Table 1. To prevent fouling the column and inlet system with the involatile portions of the crudes I have used vacuum distillation fractions of the oils, in the range 100° to 430° C, atmospheric equivalent temperature. Fig. 1*A* is a typical chromatogram of a fraction of Brega crude; the n-paraffin peaks have been labelled with their carbon numbers. (Many of these peaks have been allowed to exceed the recorder scale in order to highlight the others.)

The detailed pattern of peaks between the n-paraffins provides excellent fingerprint material. In my comparisons of different oils I have found that the most useful region lies between C_{13} and C_{19}, and the peaks which vary most in size from one oil to the next are those marked *X*. From geochemical work (ref. 5 and A. G. Douglas, private communication) it is clear that these peaks represent saturated terpenoid hydrocarbons including farnesane, pristane and phytane. The peaks immediately following those of the C_{17} and C_{18} normal paraffins explain why, on columns of poorer resolution, the C_{17} and C_{18} n-paraffin peaks appear larger than their nearest neighbours.

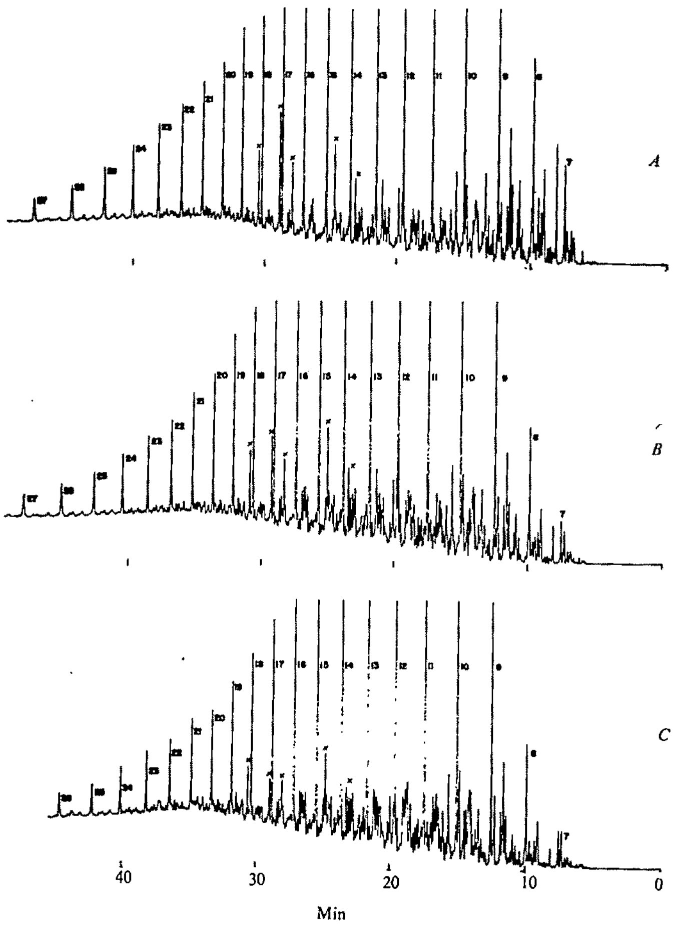

Fig. 1 Fractions of crude oils from *A*, Brega; *B*, Safaniya; *C*, Khursaniyah.

Crude oils from such diverse areas as Venezuela, Australia, Nigeria, Libya and Britain show very different fingerprint patterns, but because most crude oils shipped to Europe originate from the Middle East and North Africa, one must be able to differentiate between the oil fields of these regions if the method of recognition is to be successful.

Libyan crudes can be recognized by their large n-paraffin peaks, larger than average terpenoid peaks, and a unique pattern of the group of five peaks preceding C_{14} (Fig. 1*A*). And although all Libyan crudes which I have examined display this general trend, sufficient minor differences exist to distinguish between oils from Brega, Es Sider, Zuettina and Sarir.

Similarly the oil fields lying along the Persian Gulf between Qatar and Kuwait form a group displaying smaller terpenoid peaks and a different configuration of the five peaks mentioned above. Even so, differences can be seen between the chromatograms of Safaniya and Khursaniyah crudes (Figs. 1*B* and *C*), the locations being only 100 miles apart.

In a few cases, samples have been taken from several shipments of the same nominal crude over 6 months; the fingerprints have been identical.

In most practical situations the sample for identification is likely to be taken from the water surface or from a beach after a period of weathering. So far I have only conducted one very simple weathering test, exposing four crude oils to the elements for 1 week on top of a brine solution in metal trays. The weather during this period was very windy with alternate sunshine and rain. The original layer of oil in each tray was 5 mm thick.

At the end of the week the Brega oil, having a large proportion of light ends, had lost so much by evaporation that the layer of residue had broken up into viscous lumps with clear water between them. The others (Aramco, Kuwait, Sassan) remained as complete layers covering the water.

This artificial weathering period resulted in only minor loss of material above C_{12} and the GC fingerprints were essentially

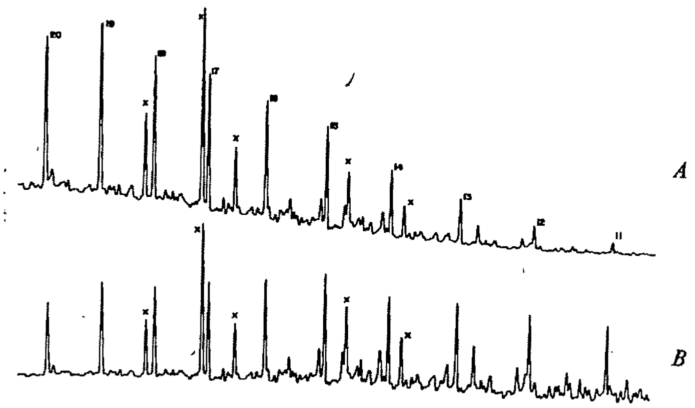

Fig. 2 Sections of chromatograms of (*A*) oil weathered for six days and (*B*) the corresponding fresh oil.

unaffected. At sea, agitation of the surface probably causes further evaporation. There is evidence, however, from the Torrey Canyon incident[3] that oil exposed for weeks or buried in sand for up to 2 yr still retains measurable quantities of material down to C_{13}.

Other processes can occur such as differential solution in water, oxidation and bacterial decay, but I do not have data on the rates of change by these means. It is reported[6] that the more volatile hydrocarbons are most soluble in water (and these will be lost by evaporation anyway) whereas, of the less volatile fractions, the aromatics are most affected. Also bacterial action may be confined almost entirely to the paraffins. The same report quotes an example of diesel oil spilled at sea, which settled into the bottom sediment and oozed out several months later; it displayed a very similar GC fingerprint (on a packed column) to the original oil.

Other views have been expressed[7], including the one that microbial action is usually confined to oil/water and oil/air interfaces so that most of a viscous lump of oil is unlikely to be degraded biologically.

The only way to determine the practical value of this technique is to apply it to spilled oils of known origin. Such samples are not readily available and so far we have been able to investigate one incident only.

After a recent tanker accident off the British coast, oil was collected off beaches up to a week later and up to 100 miles from the incident. Fig. 2 illustrates the significant sections of chromatograms of oil weathered for 6 days (*A*) and fresh oil from the stricken vessel. The principal terpenoid peaks have been marked again, and the n-paraffins numbered according to carbon atom content. The weathered oil was extracted from an aqueous emulsion with chloroform.

More than 90% of the C_{11} portion has been lost by evaporation, and diminishing losses are visible up to C_{20}. The fingerprint pattern has, however, been affected very little, even in the C_{11} to C_{13} region. This first example is very encouraging, and it is hoped to obtain further samples of this type soon. In another context, diesel oils and fuel oils have been examined in a similar way with limited success at distinguishing products from different sources. Extension of the technique to include water pollution by these products could be practicable.

Evolution of Marginal Basins

The occurrence immediately behind island arcs of small ocean basins such as the Sea of Japan and the Sea of Okhotsk is linked with the evolution of lithospheric features of the Earth, and probably the convection currents in the mantle[1]. More recent oceanographic data together with global tectonic hypotheses[2] have renewed geophysical interest in these basins. We wish to present a model for their formation and evolution.

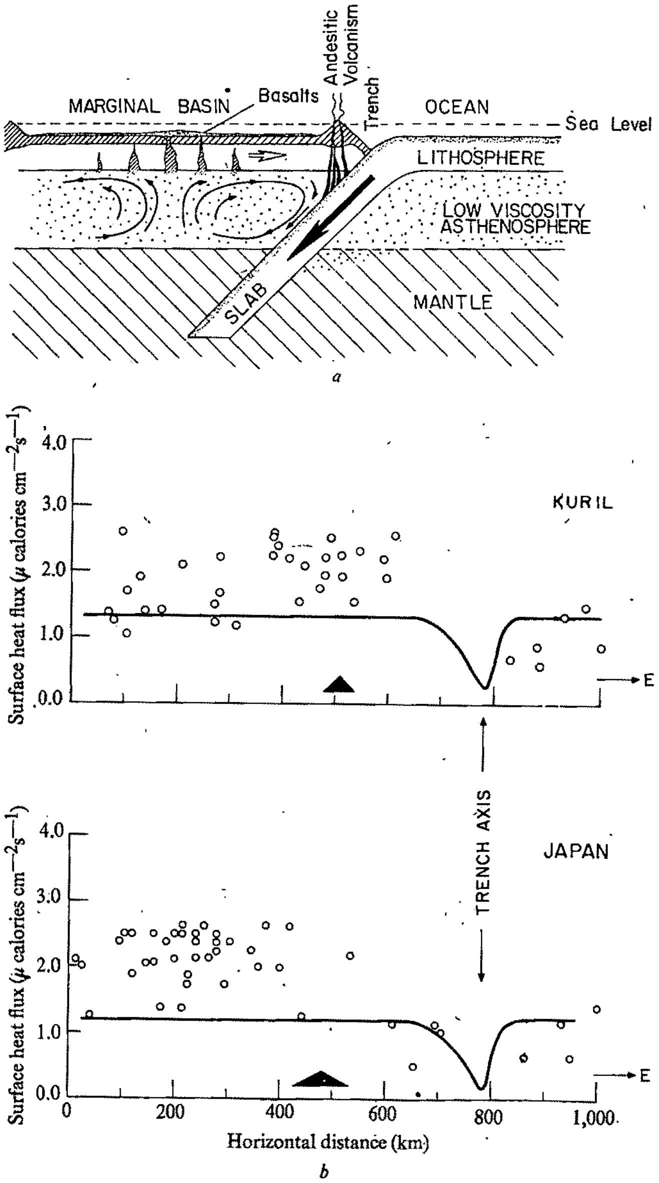

Fig. 1 *a*, Schematic diagram of the proposed mechanism. The descent of the slab causes currents in the asthenosphere which in turn cause the crustal spreading behind the island arc. *b*, Observed heat flow in the Sea of Japan and the Sea of Okhotsk plotted as a function of distance from the ridge axis. Solid line is the theoretical heat flow for a downgoing slab[19,20]. Heat transport by conduction alone cannot explain the high heat flow in the marginal basin.

Anomalously thin sediments, truncation of older geological features and freshly erupted basalts strongly support the idea[3–8] that marginal basins are the result of some type of crustal spreading. Attenuation of S_n waves[9], shallow seismicity[10] and high heat flow provide supporting evidence for relatively hot subcrustal conditions.

While some well studied, active basins such as the Sea of Japan, the Sea of Okhotsk and Lau-Harve basin have most of these characteristics, others (for example, the Bering Sea) seem to be inactive and have nearly normal heat flux and very little seismicity.

Mechanisms for the formation of the basins behind island arcs are of two kinds—trapping and spreading. The trapping hypothesis assumes that the basin behind the island arc consists of oceanic crust predating the arc, but this is inconsistent with the geophysical data. The spreading hypothesis assumes that crustal spreading is caused by the intrusion of asthenospheric material into the lithosphere behind the arc, when spreading may be triggered either by frictional heat generated by the sinking of the slab and convected to the surface[11–13] or—as proposed here—by hydrodynamic forces generated by the sinking of the slab and generating a flow pattern in the asthenosphere which in turn acts on the lithosphere. In this case, the intrusion operates independently of viscous heating and this mechanism could explain the dipping of the slab as well as explaining the above geological and geophysical data.

The model (Fig. 1) consists of a downgoing slab and a relatively low-viscosity layer (asthenosphere) sandwiched in between a rigid lithosphere and a rigid (or high viscosity) mantle. The downgoing slab generates a flow pattern by "dragging" the low viscosity material in the asthenosphere. The convective cell thus driven exerts a stress at the bottom of the lithosphere behind the island arc forcing it in the direction of the trench and causing the lithospheric opening.

This model is consistent with the upper mantle structure obtained from seismic data[14–16], where the low viscosity layer corresponds to low velocity zone, the thickness of which may vary between 100 and 250 km. "High rigidity" mantle starts at a level where the partial melting ceases. Olivine-spinel phase transformation (at a depth of about 300 to 350 km) further increases the rigidity. This rapid increase of viscosity above and below the asthenosphere is also consistent with glacial rebound data[17,18].

The motion, properties and effects of the slab have been discussed in detail[19,20]. The slab without the proposed asthenospheric convection can explain the andesitic volcanism of the island arcs, but it cannot explain the high heat flow and oceanic basalts in the marginal seas (Fig. 1*b*). The heat flow observations in the Sea of Japan and the Sea of Okhotsk are here compared with theoretical models due to the thermal regime of a downgoing slab alone. There is good agreement over the trench and near the arc, but none in the basins.

To compute the theoretical flow pattern in the asthenosphere induced by the slab we numerically solved the equation of viscous flow by a relaxation method[21]:

$$\text{grad}\, p = \eta \Delta^2 \underline{V} \qquad (1)$$

where p = pressure, η = viscosity, V = velocity. After defining a stream function Ψ such that $\Delta^2\Psi = -\text{curl}\ V = -\Omega$ where Ω is vorticity, a convergent solution was obtained by iteration. Shear stress and pressure acting at the bottom of the lithosphere ($y=0$) were found from the vorticity.

The asthenosphere was modelled as a viscous fluid bounded above and below by parallel planes. The slab was modelled as a rigid moving boundary. An artificial rigid boundary was imposed four asthenosphere thicknesses away from the slab. The flow in the region of interest is only weakly affected by this boundary[22].

The result of the calculations (Fig. 2) shows a series of recirculating eddies with only the first divergence zone being of geological interest[23] because the amplitude ratio of successive eddies is 1/350. The recirculating flow zone has two important properties. First, material is trapped in the eddy and can accumulate viscous heat through several cycles. This may be related to the origin of andesites. Second, the divergence point is a preferred place for the lithosphere to fail under tension. These features are different from the broad flow pattern of McKenzie[24].

The observed location of spreading behind island arcs[12] is where one would expect it to occur from this model, in the region near the divergence point where the stress is small. This agreement in predicted location is evidence for, but not proof of, the proposed mechanism.

The crustal spreading as described above fits the overall physical conditions of the upper mantle and the dynamics of lithospheric slab descent into the mantle. At the same time, this dynamically induced spreading explains, at least qualitatively, the geological and geophysical observations associated with active basins. The data which establish the existence of the spreading are not likely to distinguish between the different

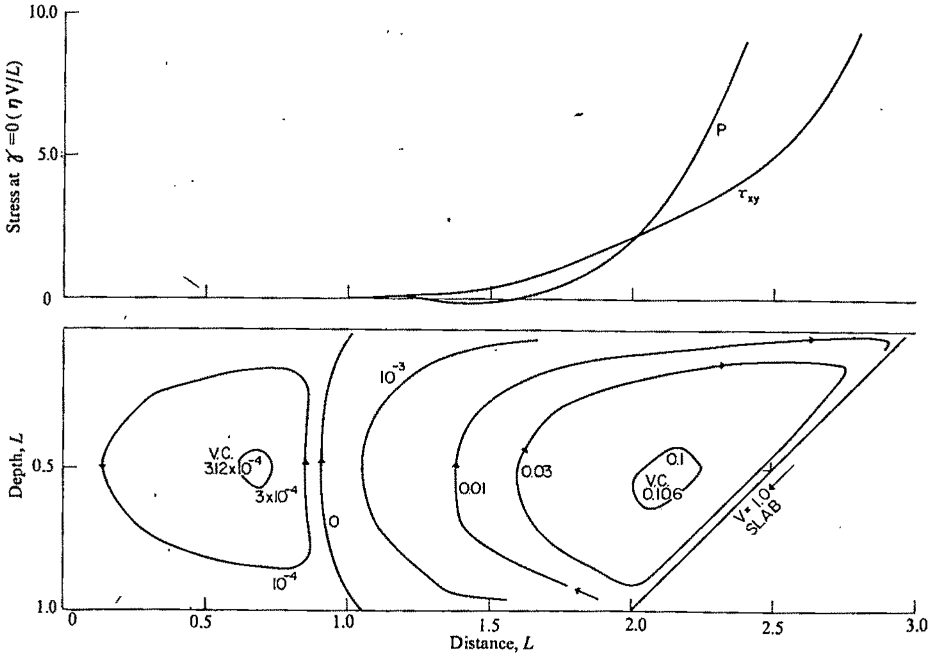

Fig. 2 Theoretical stream lines for flow in the asthenosphere. Shear stress and the vertical component of pressure along the base of the lithosphere are shown in the upper part of the figure.

mechanisms which advocate, for one reason or another, the opening of the lithosphere under the basin. One important consideration is the stress distribution shown in Fig. 2. According to our model, the lithosphere would be under tension near the centre of the basin while gradually giving way to compressive stresses toward the trench. Thus shallow earthquake mechanisms should be associated primarily with normal faulting in the centre and with reverse faulting toward the trench.

We studied the focal mechanism of two earthquakes in the Lau Basin from first-motion data. The earthquake at the centre of the basin was normal faulting (tension in horizontal direction), and the earthquake immediately behind the volcanic arc was thrust faulting (horizontal compression). A systematic study of more shallow earthquake mechanisms in the marginal basins is necessary before a meaningful evaluation of stress patterns can be made. Unfortunately, the earthquakes in the basins are small and the seismicity of this zone resembles that of the mid-ocean ridges in a smaller scale.

As the extension process continues and the basin lithosphere pushes toward the trench, the dip of the slab decreases whatever its initial descent angle. The process, however, becomes self-limiting because as the slab becomes nearly horizontal the resistance to spreading increases until the stress balance becomes compressive and the spreading ceases. A long time may be required for the slab to acquire a steeper dip under gravitational pull. Spreading is then likely to restart nearer the arc abandoning the older spreading centre.

Theoretical Evidence Against the Existence of Polywater

WE present here new results that disprove a widely discussed, and seemingly successful, structural model for polywater[1], which was derived using semi-empirical calculations, and obtained its utility by consistently correlating more than twenty experimental observations. Defeat of this model thus casts serious doubt on the existence of a new water allotrope. It is important to distinguish clearly between the essentially empirical interrelation of experiments achieved by the original model and the current attack on it, because it is obvious from ref. 1 that we have placed ourselves in the unusual and all too easy to discredit position of being authors both of the original model and of the new results against it.

The original structure model which provided a scheme for rationalizing the many diverse properties of polywater consisted of stacked layers built from hexagonal units, composed of symmetrical hydrogen bonds as proposed on qualitative grounds by Lippincott *et al.*[2]. The resulting three-dimensional polywater lattice is to ice I as graphite is to diamond, and it was found to be metastable with respect to the normal liquid. This model was derived by comparing total energies computed with a semi-empirical molecular orbital model for a very large number of possible geometrical arrangements of oxygen and hydrogen atoms. The resulting structure gave a lower internal energy than other proposed arrangements, and it made plausible the experimental measurements of infrared and Raman absorption frequencies, proton magnetic resonance frequency shift, optical excitation, viscosity, density, index of refraction, vapour pressure, high and low temperature behaviour, X-ray diffraction line spacings, nuclear magnetic resonance line shape versus temperature, electrical conductivity, optical anisotropy, deuterium exchange rate with normal water, high frequency dielectric constant and absorption, surface tension, oxygen inner-shell ionization potential shift relative to the normal liquid, and the predominance of ionic over neutral impurities.

To test whether or not this model could exist as a metastable state, the smallest representative group of atoms—a single hexagonal unit $(H_2O)_6$ with hydrogen atoms symmetrically placed around the ring between the oxygen atoms—was studied with *ab initio* molecular orbital calculations augmented by zero point and correlation energy corrections[3]. The quantitative validity of these wavefunctions for determining binding energies was verified by calculations on well established asymmetrically bonded polymers of water and hydrogen fluoride. Our computations yielded values within the range of experimental error for each of the known polymers (H_2O and HF dimers, cyclic $(HF)_4$ and $(HF)_6$). Thus we have confidence in the results showing symmetrically bonded hydrogen fluoride and water to be 1 or 2 kcalories/H-bond more stable than six monomers, but approximately 5 kcalories/H-bond less stable than the corresponding asymmetric structures. The semi-empirical calculations in the original model[1] show the same relative ordering of energies, but the symmetric structures are placed only very slightly above the asymmetric ones. Analysis of the errors inherent to the semi-empirical method reveals that its tendency to produce too short bond distances, in such cases as the $O \cdots O$ separation in the water dimer, leads to an unrealistic lowering of the total energy for symmetrical hydrogen bonds.

The wall attachment process was a central feature of the original model, and because of the large energy separation between symmetric and asymmetric hydrogen bonds noted above, we have extended the original semi-empirical surface model calculations to greater distances from the wall. Going out from the surface, the oxygen atoms carry charges of 8.37, 8.46 and 8.49. When compared with an isolated cyclic symmetric hexamer (oxygen charge 8.47), it is apparent that the surface is inducing a very small oscillatory charge redistribution that completely damps out in a few layers. Charges on the symmetrical hydrogen atoms show a parallel behaviour. Charged ions (for example, Na^+) may also play a role in the surface effects, and we have made semi-empirical calculations for the close approach of Na^+ to both oxygen and hydrogen in a water molecule. Here again the charge redistribution is relatively small, and a long-range stabilization is precluded. To span the inner diameter of 10–100 μm capillaries with anomalous material requires a wall effect extending out more than 100,000 layers, and this is completely ruled out.

In addition to the two theoretical results discussed in the above paragraphs, a recent molecular weight measurement in Derjaguin's laboratory[4,5] cannot be accommodated by our original model. Not only is their value of 180 considerably less than implied by the original model, but the one or two-ring structure required by Derjaguin's measurements raises an even more serious objection. The higher energy of the symmetric bonds permits a one-ring or two-ring structure to rearrange to the lower energy conventional asymmetric bonds. This prevents realization of the kinetic barrier postulated for the more complex, three dimensional original model structure.

From the results presented above we conclude that a new allotrope of water does not exist. Our argument is based on disproof of the model which appeared to offer a consistent and compelling rationalization of the formation and twenty-odd properties of polywater. Finally, the position we take in this letter is clearly opposite to that in our original work.

BIOLOGICAL SCIENCES

New Approach to the Synthesis of Polyribonucleotides of Defined Sequence

SOME of the problems associated with the chemical synthesis of polynucleotides are the lower yields obtained in the synthesis of larger oligonucleotides and the considerable labour involved in their preparation and purification because of the necessity for chemical protection of the bases and the occurrence of side reactions during synthesis[1]. We have developed a new method of synthesis of polynucleotides containing well defined sequences which promises to avoid some of these difficulties. The basis of the method lies in the use of a nucleotide polymerizing enzyme with substrates containing chemical modifications such that only one nucleotide at a time would be permitted to add to a growing polynucleotide strand.

We have studied nucleoside 5′-diphosphates and the enzyme, polynucleotide phosphorylase, which catalyses the successive transfer of the nucleoside 5′-phosphoryl moiety from the substrate to the 3′-hydroxyl group of a polyribonucleotide chain. A number of nucleotide 5′-diphosphates containing chemical blocks at their 2′ and 3′-positions have been synthesized with expectation that, if the modified nucleotide were transferred to the 3′-terminus of a polynucleotide, the presence of the blocking group would prevent any further enzymatic addition. Subsequently, the blocking group could be removed and a second single addition effected and so on. The choice of blocking group is subject to several considerations: (i) it should be chemically stable in the conditions of the enzyme reaction, (ii) the removal of the blocking group should be possible in chemical conditions which would not affect the structural integrity of the synthesized polymer, (iii) the group should be sufficiently small for the modified diphosphates to be accepted as substrates by the enzyme, (iv) it should be of such size and configurations that a polynucleotide chain containing the group at its 3′-terminus would be totally resistant to further enzymatic addition.

Nucleoside 5′-diphosphates containing the following blocking groups have been synthesized: 2′(3′)-0-(α-methoxyethyl), 2′,3′-cyclic carbonate, 2′,3′-0-methoxymethylidene, 2′(3′)-0-acetyl, and 2′,3′-cyclic phosphate. 2′(3′)-0-(α-Methoxyethyl) nucleoside 5′-diphosphates (I) were prepared by the direct acid catalysed reaction of each nucleoside diphosphate with methyl vinyl ether.

(Other α,β-unsaturated ethers, Δ^2-dihydropyran and ethyl vinyl ether, have already been exploited for the blocking of hydroxylic functions in nucleotides[2–4].) The nucleoside 5′-diphosphate (0.5 mmol) and toluene-sulphonic acid (2.5 mmol) are dissolved in dimethylsulphoxide (4 ml.) and frozen by immersion in an ice bath. Methyl vinyl ether (8 ml.) at 0° C is added and the two components mixed thoroughly. In the case of guanosine 5′-diphosphate it is advisable to use a slightly higher ratio of dimethylsulphoxide to methyl vinyl ether to avoid precipitation of the nucleotide. The liquid mixture is kept at 0° C for 10 min and the reaction is then stopped by the addition of concentrated ammonia (1 ml.). The solution is slowly warmed to room temperature to remove the excess methyl vinyl ether and the product streaked on Whatman 3 MM chromatographic paper (80 cm). Chromatographic separation with the solvent system, n-propyl alcohol–concentrated ammonia–water (55 : 10 : 35), gives three nucleotide bands which contain, in order of decreasing R_F, 2′,3′-di-0-(α-methoxyethyl)nucleoside 5′-diphosphate, 2′(3′)-0-(α-methoxyethyl)nucleoside 5′-diphosphate and nucleoside 5′-diphosphate. The monosubstituted product, which is obtained in yields of 25–50%, is cut out, eluted with water and concentrated. The stability of the blocking group was studied using 2′(3′)-0-(α-methoxyethyl)adenosine 5′-phosphate prepared in a similar way. The α-methoxyethyl group in this compound was found to be quite stable at *p*H 9 and was completely removed by treatment at *p*H 2 for 15 min at 37° C or at *p*H 3 for 90 min at 37° C.

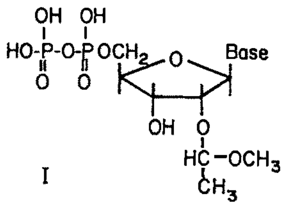
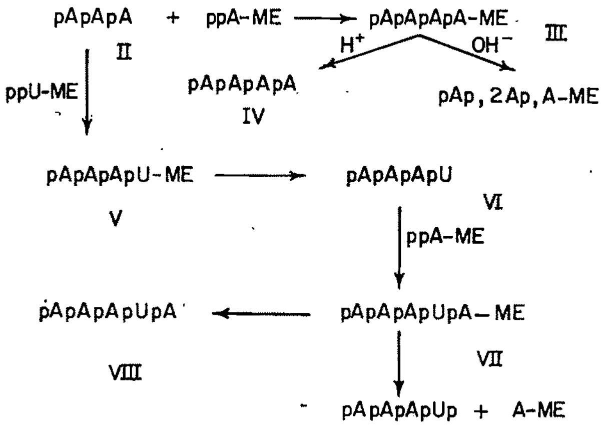
CALCUTTA



I



A typical reaction mixture consists of the primer or acceptor molecule (0.4 μmol), 2′(3′)-0-(α-methoxyethyl)nucleoside 5′-diphosphate (1.2 μmol), Tris-chloride buffer, *p*H 9.0 (20 μmol), $MnCl_2$ (2 μmol) and the enzyme (2 units) in a total volume of 0.2 ml. The *E. coli* polynucleotide phosphorylase was obtained from General Biochemicals, Chagrin Falls, Ohio, and the unit is defined as that amount of enzyme which catalyses the incorporation of 1 μmol of adenylic acid into polymer/h at 37° C. The reaction mixture is incubated at 37° C for 7 h and then applied to a DEAE-'Sephadex A-25' column (0.5 × 20 cm) and separation is carried out with a triethylammonium bicarbonate gradient (0.1 M to 1.0 M in 300 ml.). The product is collected and concentrated to dryness to remove the volatile eluting salt. To remove the terminal 2′(3′)-blocking group a solution of the nucleotide is brought to *p*H 2 or 3 with dilute hydrochloric acid and kept at 37° C for 15 min or 90 min respectively. After this treatment the polynucleotide is ready for a further enzymatic reaction.

We used as the primer or acceptor molecule adenosine trinucleotide (II) prepared by the degradation of polyadenylic acid with pork liver nuclease[5] followed by fractionation of the products by ion-exchange chromatography. In the presence of the enzyme and 2′(3′)-0-(α-methoxyethyl)adenosine 5′-diphosphate (ppA-ME) the trinucleotide was completely converted into the blocked tetranucleotide, III. The structure of this product was proved by the analysis of its elution position on ion exchange chromatography, by chromatography on a dihydroxyboryl-substituted cellulose derivative, and by chemical degradation to its components. The product was not retained by a column of N-(*m*-dihydroxyborylphenyl)carbamylmethylcellulose indicating that the molecule did not possess a free 2′,3′-*cis* glycol group at its 3′-terminus[6,7]. But after the polynucleotide had been treated with mild acid (to produce the adenosine tetranucleotide, IV) it was strongly bound to a column of the substituted cellulose. On degradation with alkali in standard conditions oligonucleotide, III, gave a mixture of components which were separated by 'Dowex' 1 × 2 ion exchange chromatography. The products, adenosine 2′(3′),5′-diphosphate, adenosine 2′(3′)-phosphate, and 2′(3′)-0-(α-methoxyethyl)adenosine were obtained in a ratio of 1.0 : 2.0 : 1.0. The identity of the nucleoside obtained in this hydrolysis was confirmed by comparison of its paper chromatographic R_F values with those of an authentic derivative obtained from 2′(3′)-0-(α-methoxyethyl)adenosine 5′-phosphate by dephosphorylation with bacterial alkaline phosphatase. The two solvent systems used for the comparison were n-propyl alcohol–concentrated ammonia–water (55 : 10 : 35), and 0.1 M sodium phosphate, *p*H 7 (100 ml.) + ammonium sulphate (40 g). In the former system the substituted adenosine has R_F 0.80, while in the latter system the derivative splits into two spots with R_F values 0.17 and 0.10, presumably the 2′- and 3′-isomers. The predominant nucleoside obtained from the terminus of III was identical to that isomer which has R_F 0.17 in the ammonium sulphate solvent system. Thus, although both 2′- and 3′-substituted adenosine diphosphates are available in the addition reaction mixture, the enzyme incorporates one of these isomers preferentially. Preliminary mass spectral data suggest that the 2′-0-(α-methoxyethyl)-adenosine 5′-diphosphate is the preferred substrate, and unambiguous synthesis of both 2′- and 3′-(α-methoxyethyl)-adenosine are now being carried out to confirm the structure of the blocked terminal nucleoside present in the tetranucleotide, III.

To demonstrate the technique of successive addition a pentanucleotide has been prepared. The trinucleotide, II, was reacted with 2′(3′)-0-(α-methoxyethyl)uridine 5′-diphosphate (ppU-ME) to quantitatively yield the blocked tetranucleotide, V. Fig. 1 shows the elution patterns from the analysis of this reaction. Elution pattern B exhibits the typical shift in the elution position of the polynucleotide on increasing its chain length by one nucleotide unit. No trace of the acceptor molecule, II, remains after the enzyme reaction. The small peak preceding the nucleoside diphosphate peak in each case is due to small amounts of substituted nucleoside 5′-phosphate which is a contaminant of the substituted nucleoside 5′-diphosphate. These substances do not, however, affect the enzyme reaction and it is not necessary to remove them from the nucleoside diphosphate substrate beforehand. The blocked tetranucleotide, V, was converted to its unblocked form, VI, by mild acid treatment and used as the acceptor molecule for a second addition. On treatment with enzyme and the blocked adenosine diphosphate it was converted quantitatively into the blocked pentanucleotide, VII (Fig. 1). The molecule was then hydrolysed to the unblocked product, VIII, by mild acid treatment. The structure of the blocked pentanucleotide, VII, was confirmed by hydrolysis with pancreatic ribonuclease. The release of 2′(3′)-0-(α-methoxyethyl)adenosine by this enzyme showed that a uridine moiety was located at the penultimate position of the pentanucleotide and that the 3′-terminal nucleoside was a blocked adenosine.

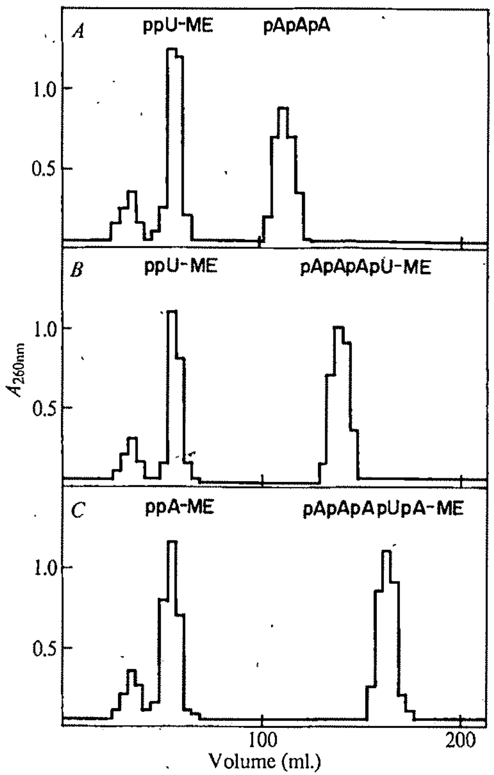


Fig. 1 Elution patterns from the DEAE-'Sephadex A-25' column chromatography of enzyme reaction mixtures. The columns (0.5 × 20 cm) were eluted at 20° C with a gradient of triethylammonium bicarbonate buffer (0.1 M to 1.0 M in 300 ml.) at a flow rate of 15 ml./h. *A*, Elution pattern for a reaction mixture containing the adenosine trinucleotide, II, and 2′(3′)-0-(α-methoxyethyl)uridine 5′-diphosphate but no enzyme. *B*, Elution pattern for the products of the reaction of the adenosine trinucleotide, II, and 2′(3′)-0-(α-methoxyethyl)uridine 5′-diphosphate with polynucleotide phosphorylase. *C*, Elution pattern for the products of the reaction of the tetranucleotide, VI, and 2′(3′)-0-(α-methoxyethyl)adenosine 5′-diphosphate with polynucleotide phosphorylase.

Preliminary experiments with the α-methoxyethyl derivatives of cytidine and guanosine diphosphates have shown that it is also possible to add these nucleotides enzymatically to an acceptor molecule in a way similar to that we have described for the adenosine and uridine derivatives.

To determine the generality of our new synthetic method, experiments are now in progress to measure the efficiency of the addition reaction with acceptor molecules containing various chain lengths and nucleotide sequences. Further work has begun on the development of a solid support system to be used in an automated synthetic machine. The problems under investigation are the method of attachment to the solid support of the initial acceptor molecule and the incorporation of a chemically induced release mechanism for the separation of the polynucleotide from the solid support after synthesis.

Application of Computer Experimentation to the Cornea

BECAUSE of the variability of tissue culture samples, it is often impossible or impractical to measure precisely all the relevant dependent variables under a selected set of conditions. Computer modelling is an attractive technique for studying complicated structures in complex environments, because of the perfect reproducibility of the results and the precision with which all the characteristics (fluxes, internal compositions, potentials) of the tissue are self-consistently determined. The accuracy is of course no better than those input tissue properties to which the answers are most sensitive.

To illustrate the capabilities of this approach, a computer model of the cornea has been used to examine the implications of Green's[1] measurements of the variation of the short-circuit current (SCC) of the isolated rabbit cornea as the sodium content of the media bathing both the epithelial and endothelial surfaces is replaced in part by potassium and as the sodium bathing the epithelial surface is further replaced by choline. It is generally accepted[2–4] that the current is generated by a sodium pump in the epithelium; pumping is from the tear film towards the stroma. Tracer studies[3] on isolated endothelium have revealed no difference between the unidirectional fluxes of sodium or chloride across this tissue; accordingly, the epithelial sodium pump was assumed to be the sole operative active transport mechanism.

The model properties of the cornea are given in Table 1. Table 2 gives the composition of the solutions bounding the cornea and the values of SCC measured by Green[1]. Green's measurements were made on a series membrane system (in the antero-posterior direction, epithelium–stroma–endothelium) across which there were, except for cases 1 and 2, concentration gradients. Thus, the usual identification of the epithelial pump rate, *P*, with SCC is inappropriate[13,14].

Although the identity *P*=SCC is in error here, the pump rate can still be found from the flux equations, but the solution is not explicit. In setting up the problem, the corneal current density, I, and the compositions of the bounding solutions $\{c_j\}_1$ (epithelial bath) and $\{c_j\}_3$ (endothelial bath) are known, and a value of *P* is assumed. In the steady state the gross flux X_j of the *j*-th ion is the same in each layer. The gross fluxes corresponding to the given *I*, $\{c_j\}_1$, $\{c_j\}_3$ and *P* were obtained by starting with the given values of $\{c_j\}_1$ at the epithelial surface and finding the values of $\{X_j\}$ such that the calculated current density equalled *I*, and the endothelial composition was $\{c_j\}_3$. The intracorneal compositions and membrane potentials are also found as a matter of course. To carry out the calculation, two classes of solutions were developed. The description of multiionic passive transport[15] needed to "cross" each layer and the general Donnan condition[16] used at the stromal interfaces have been presented elsewhere. The flux equations[15] are based on the frictional formulation[17] of irreversible thermodynamics, include direct interactions between oppositely-charged ions, and may be regarded as generalized from the Nernst-Planck form. The passive fluxes

(*a*) Phenomenological resistance measuring direct interactions between oppositely-charged ions. $\bar{R}$ and f_j (*e* below) are defined by $-\mathrm{d}\tilde{\mu}_j/\mathrm{d}x = -\sum_{i(z_i=-z_j)} \bar{R}(J_jc_i/c_j - J_i) + f_jJ_j/c_j$ where *i* and *j* index the ions, $\tilde{\mu}$ is electrochemical potential, *x* is distance through the membrane, *z* is ionic charge, *J* is passive flux, and *c* is concentration. See ref. 7 for detailed discussion. (*b*) Donn *et al.*[5] measured the self-diffusion of HTO through the corneal membranes. Their data were used to estimate the effective membrane tortuosity, which was then used to obtain the needed *R* from the pure saline data in (*c*). The value of $\bar{R}$ given here is likely to be an overestimate: in any event the influence of ion–ion interactions is small in the epithelium and endothelium, where the solute–membrane interaction is large. (*c*) Katchalsky and Curran[6]: the value of $\bar{R}$ in the stroma is found from that in saline. (*d*) Maurice[7] gives the obstruction of stroma and endothelium to diffusion; this obstruction applied to known friction coefficients (*c*) in saline. (*e*) Phenomenological friction coefficient[8] measuring solvent and membrane drag. See (*a*) for defining equation. (*f*) Green[9]: tracer measurement. (*g*) Based on friction coefficient of sodium, assuming *f* inversely proportional to limiting mobility at infinite dilution; mobility values from Edsall and Wyman[10]. (*h*) Similar to (*g*); based on friction coefficient of chloride. (*i*) K. Green, private communication; tracer measurement. (*j*) Friction coefficient of choline equated to that of bicarbonate. (*k*) Maurice[11]. (*l*) Trenberth and Mishima[12]. (*m*) The stromal thickness used throughout is the normal value, though in some of the experiments *in vitro* to be modelled here, the cornea was swollen. The stroma is so permeable that the electrical properties of the entire cornea are essentially independent of stromal thickness over the range of interest. (*n*) M. H. Friedman and K. Green, unpublished work. This is a preliminary experimental value. The results presented in the text are insensitive to the stromal charge density between zero and the value used here.

3	$\mathrm{II_{18}}$	$\mathrm{II_0}$	6.95×10^{-11}
4	$\mathrm{II_{58}}$	$\mathrm{II_0}$	5.00×10^{-11}
5	$\mathrm{II_{98}}$	$\mathrm{II_0}$	2.78×10^{-11}
6	$\mathrm{II_{113}}$	$\mathrm{II_0}$	1.111×10^{-11}

All concentrations are in mequiv. l.$^{-1}$.

* Positive ion flux, tears to aqueous. These values do not reflect Green's[1] experimental precision; the "insignificant" digits are a consequence of converting his results to c.g.s. units.

on which these equations operate are given by $J_{jk}=X_j-P_{jk}$ where J_{jk} (or P_{jk}) is the passive (or pump) flux of j through the k-th corneal layer. In the present study, the only non-zero P_{jk} is P_{Na}, epithelium$=P$.

To interpret Green's short-circuit data, I was equated to SCC, and the value of P was found for which the transcorneal potential ψ was zero. These values and the SCC are plotted in Fig. 1 against the sodium content of the epithelial bath. It can be seen that there is no evidence that the epithelial pump rate is sensitive to the sodium content of the epithelial bath over the range of compositions studied. The average value of P, based on the computer results for cases 1–4 and 6, is $(10.3\pm0.6)\times10^{-11}$ equiv. cm^{-2} s.

To test the conclusions of the short-circuit simulations, cases 1–6 were re-run under open circuit conditions ($I=0$) with $P=10.3\times10^{-11}$ equiv. cm^{-2} s, to give ψ. The calculated transcorneal potentials are shown in Fig. 2 with the transcorneal potentials measured *in vitro* (Green, private communication) for each case. Recognizing that the simulator calculation of ψ is based on the measured properties of the corneal membranes and on a value of P calculated from other experimental data, the agreement in Fig. 2 is really quite good.

Green found[1] that as the sodium concentration in the epithelial bath was reduced, the cornea swelled to larger equilibrium thicknesses. This might most readily be explained as the consequence of a concomitant increase in the osmolarity of the stromal fluid, a hypothesis which is unfortunately contradicted by the results of the computer experiments. The replacement of 25 mequiv. Na by K on both corneal surfaces (case 2 *vs* case 1) has a minor effect on the stromal osmolarity when $I=0$; it is 306.3 (posterior stroma)—306.8 (anterior stroma) mOsm l.$^{-1}$ in both cases. Continued replacement of sodium by choline on the epithelial side, however, results in a drop in stromal osmolarity, even though no decrease in pump current is assumed. In case 6 the stroma contains 300.2–300.4 mOsm l.$^{-1}$. The free sodium content of the stroma drops correspondingly from 139.0–139.3 mequiv. l.$^{-1}$ in case 2 to 133.8 mequiv. l.$^{-2}$ in case 6. The decrease in stromal tonicity as sodium is removed from the epithelial bath represents a considerable decrease in stromal osmotic pressure—a change opposite to that required to explain Green's results on osmotic grounds.

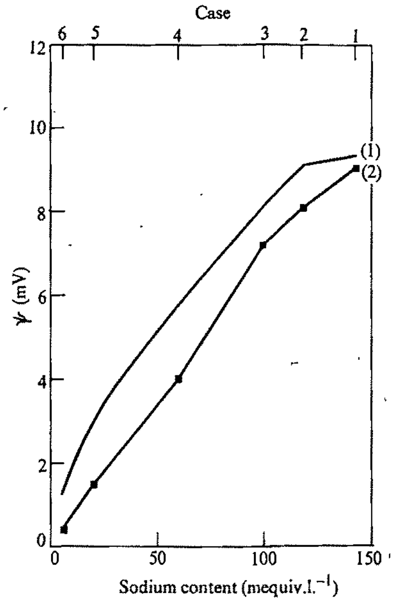

Fig. 2 Open circuit corneal potential (ψ) *vs* sodium content of the epithelial bath. (1) Computed transcorneal potential, $P=10.3\times10^{-11}$ equiv. cm^{-2} s; (2) experimental transcorneal potential.

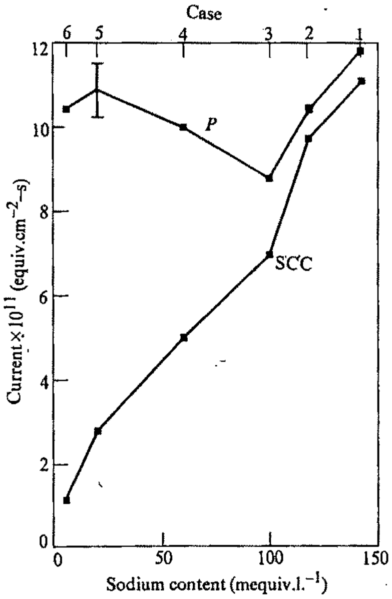

Fig. 1 Measured short-circuit current (SCC) and computed epithelial pump current (P) *vs* sodium content of the epithelial bath. Convergence difficulties permitted only a range of values of P to be found for case 5.

CALCUTTA

A principal role of model building is the testing of hypotheses, in the present case the hypothesis[1] that the epithelial sodium pump is implicated in the control of corneal hydration. This view has been contested by other corneal physiologists[18-20], who are supported by the results of the present work, which shows that the pump rate is not changed in the experiments in which a decrease in epithelial sodium was shown to induce swelling. If the pump rate were to fall as $c_{\mathrm{Na},1}$ was lowered, the stromal tonicity would decrease even more rapidly than found here. It follows that the corneal swelling produced by the replacement of sodium by choline in the epithelial bath is not pump-related and indeed does not appear to be osmotic in origin. The possibility of trauma cannot be discounted in such nonphysiologic environments; measurements of epithelial permeability in choline-containing solutions would surely be of interest.

The interaction between computer and physical experiments is symbiotic and the combined technique can be used to study a wide variety of biological systems; the computer program used here to investigate the cornea is directly applicable to other tissues, such as frog skin, which can be represented as series plane–parallel membrane structures. Geometric variations from the plane–parallel case should offer no difficulty, and more structurally complex systems should also be susceptible to this approach. The computer experiments rely on the results of physical experimentation in that the latter yield the property data (membrane permeabilities) used by the former, and because the physical experiments provide the essential phenomenological data for analysis (variation of SCC with $c_{\mathrm{Na},1}$) and which serve to check the results of the modelling (ψ). The computer supports the physical experimentation by allowing the study of complex systems in realistically complex environments, reducing questions of artefact and trauma. In addition, the computer experiments can generate data (stromal tonicity variations) to whose values tissue behaviour (swelling) is highly sensitive but which cannot be found well enough experimentally. Finally, the results of the computer experiments can identify critical physical experiments (variation of epithelial permeability with ambient composition), whose results can further illuminate the problem at hand. This synergism makes the combination of physical and computer experiments a powerful combined approach to the study of biological systems.

I thank K. Green for supplying choline permeabilities and corneal potential data *in vitro*. The computer programming and execution services were provided by Mary E. Lynam.

This investigation was supported by the National Institute of Neurological Diseases and Stroke, National Institutes of Health, US Public Health Service.

Non-Identity of Apparently Similar Chromosome Aberrations in Human Lymphoblastoid Cell Lines

A FEW chromosome aberrations seem to recur with significant frequency among the many aneuploid human lymphoblastoid lines established from various sources. (For discussion and references see ref. 1.) These include trisomy *C*, a marker chromosome ("m_B") larger than the chromosomes of group 4/5 but with a similar arm ratio and an acrocentric marker ("m_D") similar to an enlarged *D* group chromosome.

Since clones of cells bearing one or more of these abnormalities seem to have a selective advantage for growth *in vitro* it is important to know whether these apparently morphologically identical abnormalities consist of the same genetic material in each case. By using quinacrine fluorescence[2,3] to identify features specific to particular chromosomes in the human complement we can answer this question. Chromosomes in cells from fourteen lymphoblastoid lines, which originated in this laboratory or had been maintained here for more than 1 yr (Table 1), were examined by a technique described before[3].

From each line karyotypes from photographs of four to twelve metaphase spreads, showing good fluorescent banding patterns, have been studied in detail. In most of the aneuploid lines, the amount of chromosomal rearrangement revealed by quinacrine staining is greater than could be anticipated from orcein preparations, and some lines are composed of several distinct clones. In these cases, many more cells require to be examined before the definitive karyotype can be established. From the preliminary studies, however, the following results have been obtained.

Trisomy *C* was detected, on orcein staining, in lines JIYOYE and F137. In each of the seven JIYOYE cells examined with fluorescence there was trisomy of the number 9 chromosome and an additional metacentric, about the size of a number 16 which appeared to be composed of a number 7 chromosome with partial deletion of the long arm (partial trisomy 7) (Fig. 1*a*).

Twelve F137 cells have been photographed. In eight of these there was an extra chromosome morphologically belonging to group *C*. In five cases this was due to trisomy 7 (Fig. 1*b*) but in the other three the extra chromosome seemed to have been derived from a number 3 by partial deletion of one arm (Fig. 1*c*). In all five cells with trisomy 7, two of the number 7 chromosomes had a prominent subterminal secondary constriction on the long arm. This was not present in the other lines examined. An abnormality of this type has been reported in many cell lines, its frequency apparently depending on the technique used to establish each culture (see refs. 1 and 5 for further refs.).

Table 1 Cell Lines Examined

Line	Source	Modal chromosome number	Diploid or aneuploid on orcein staining
JIYOYE*	Burkitt's lymphoma	48–50	Aneuploid
RAJI*	Burkitt's lymphoma	46	Aneuploid
F137†‡	Chronic lymphatic leukaemia	47	Aneuploid
F89†‡	Subacute lymphatic leukaemia	46	Aneuploid
GOL_1‡§	Infectious mononucleosis	46	Aneuploid
$G\text{-}S_1$‡§	Chronic lymphatic leukaemia	47	Aneuploid

Trisomy 7 was also present in all five RAJI cells examined. This could not have been predicted from the orcein preparations since another *C* group chromosome (number 8) was missing from every cell (Fig. 1*d*).

Three examples of marker m_B occurred among the eight aneuploid lines. Two were present in every $G\text{-}S_1$ cell and one in each RAJI cell. The fluorescent banding patterns showed that each had been formed in a different way.

One of the pair in $G\text{-}S_1$ appeared to match, in the centromere and proximal part of the long arm, with a number 3 chromosome and the distal part of the long arm was probably derived from a number 7. This line is monosomic for chromosomes 3 and 7. The other marker in $G\text{-}S_1$ corresponded to a number 4 with additional, brightly fluorescent, material on the end of the long arm. In RAJI the marker also seemed to be derived from a number 4 but the extra material at the end of the long arm appeared very dark on quinacrine staining (Fig. 1*e*–*f*).

An enlarged *D* chromosome was a feature of every cell of lines JIYOYE, F137, F89 and GOL_1. In JIYOYE marker m_D was derived from a number 14 (Fig. 1*g*), and in F89 and GOL_1 from a number 13. The latter two, however, had quite different banding patterns (Fig. 1*h* and *j*). Ten of the twelve F137 cells had a large number 13 (Fig. 1*k*) but in four cells there was one member of the 14 pair which was almost as large (Fig. 1*l*). In one cell from this line a number 14 was clearly the largest and there was a partial deletion of a number 13, possibly representing a 13/14 translocation (Fig. 1*m*).

In this relatively small sample of aneuploid lines, the apparently similar recurrent aberrations Trisomy *C*, m_B and m_D have each evolved in at least three different ways. It seems likely therefore that aneuploidy arises in lymphoblastoid cells by a wide variety of non-disjunctional, breakage and

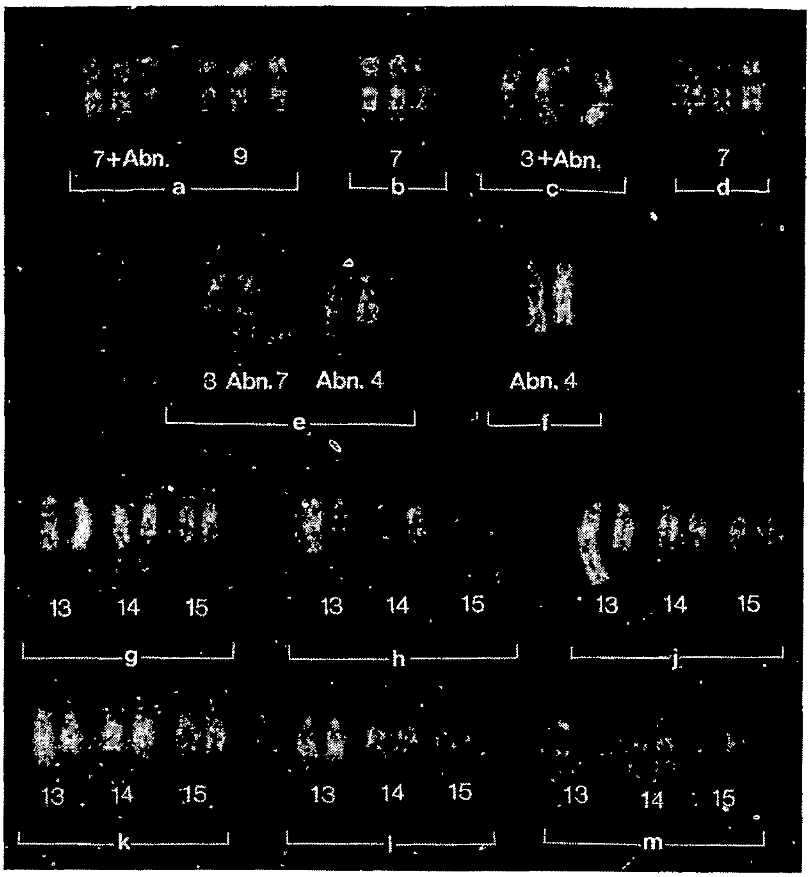

Fig. 1 The chromosomes in each group, *a*–*m*, are from a single cell. *a*, JIYOYE: trisomy 9 and partial trisomy 7. *b*, F137: trisomy 7. Two of the chromosomes show a prominent subterminal secondary constriction of the long arm. *c*, F137: abnormal chromosome, morphologically belonging to group *C* but, on banding pattern, probably derived from a number 3 as shown. *d*, RAJI: trisomy 7. *e*, G-S$_1$: two abnormal chromosomes of type "m_B", one probably derived from a number 3 and a number 7, the other from a number 4. *f*, RAJI: an abnormal chromosome of type "m_B" probably derived from a number 4 with additional non-fluorescent material on the long arm. *g*, JIYOYE: the chromosomes of group *D*, showing enlargement of a number 14. *h*, F89: the chromosomes of group *D*, showing enlargement of a number 13. *j*, GOL$_1$: the chromosomes of group *D*, showing enlargement of a number 13. (Probably duplication of the long arm.) *k*, F137: the chromosomes of group *D*, showing enlargement of a number 13. *l*, F137: the chromosomes of group *D*, showing enlargement of a number 13 and of a number 14. *m*, F137: the chromosomes of group *D*, showing probable 13/14 translocation.

recombination events, so that the apparent recurrence of distinctive markers in several lines reflects chiefly the limitations of standard staining techniques for the identification of individual chromosomes. These limitations apply not only to obviously aneuploid lines since it is theoretically possible for major rearrangements of genetic material to be concealed in an apparently diploid karyotype. No abnormality has yet been detected, however, on constructing quinacrine fluorescence karyotypes of the six diploid lines listed in Table 1.

In permanent human cell lines, all chromosomes may not be equally susceptible to loss, reduplication or breakage while it is likely that certain aberrations have a more profound effect than others on the viability of the involved cell and its progeny. Thus, for example, an abnormality involving chromosome number 7 was present in four of the eight aneuploid lines in this series. Since up to twelve separate aberrations could be recognized in each cell of any one line, however, there may be more significance in the fact that a normal pair of numbers 1, 10, 15, 17, 18, 20 and 22 was present in every line and no reduplication of these chromosomes could be detected. More definite information on the frequency (and importance to the cell) of aberrations affecting the different chromosomes of the human complement should prove to be one of the most interesting outcomes of further studies along these lines.

Detection of Human Leukaemia Associated Antigens in Leukaemic Serum and Normal Embryos

THE occurrence of tumours or leukaemia in experimental animals is frequently associated with the appearance of "new" antigens perhaps indicative of gene activation or mutation, or infection with oncogenic virus. The reliable detection of such antigens in man would provide an immunological signal of incipient tumour formation and might permit early or more precise diagnosis. The study of human tumour antigens might also be expected to yield information about the causes and natural history of human cancer as well as suggest improved means of treatment. This communication is concerned with the detection of one group of "new" antigens, those associated with human leukaemia.

We have previously shown that leukaemic cells will induce transformation of autologous lymphocytes *in vitro* and that a reaction of increased intensity can be obtained by immunizing a patient during remission with his own leukaemic cells taken during relapse and stored in liquid nitrogen[1]. We concluded that "new" antigens occurring in leukaemia were not recognized as "self" by autologous lymphocytes and this view has been supported by Powles *et al.*[2] and other workers[3,4] using similar methods. We have identified, solubilized and partially purified leukaemia associated antigens (LAA) obtained from human leukaemic cells[5] and, using xenogeneic antisera, have demonstrated that LAA may also be detected in the serum of patients with leukaemia and in embryos[6].

Full details of the techniques of antigen extraction and solubilization and of rabbit immunization and serum preparation have been described elsewhere[5-9]. We used the double diffusion technique (DD) as used previously[5,6] and in addition cross over electrophoresis (COE)[10-12] for the rapid detection of LAA in human serum. In this latter technique rabbit antiserum was placed in the anodal well and human test serum in the cathodal well. The agar plates were then subjected to a potential difference of 9.5 V cm^{-2} for 15 min. After washing and overnight drying, slides were stained by a very brief immersion in amido-black.

Table 1 Double Diffusion (DD) and Cross Over Electrophoresis (COE) Positive Reactions obtained using Absorbed Rabbit Antiserum FXP and Serum Concentrated Three Times from Patients

Diagnosis	No. of patients tested	No. of positive reactions	
		DD	COE
AML	14	1	5
CML	6	0	3
ALL	3	0	2
CLL	13	1	2
Chronic monocytic leukaemia	1	0	0
Hodgkin's	11	0	3
Myelofibrosis	1	0	0
Primary hepatoma	1	0	0
Total	50	2	15

AML, Acute myeloblastic leukaemia; CML, chronic myeloid leukaemia; ALL, acute lymphoblastic leukaemia; CLL, chronic lymphocytic leukaemia.

Using a suitably absorbed xenogeneic antiserum, FXP prepared against material extracted from acute myeloblastic leukaemia cells, about one-third of patients with leukaemia could be shown to have circulating LAA in their serum (Table 1); LAA do not necessarily disappear in haematological remission. When DD was used, positive reactions were associated with two or more precipitation lines[5,6]. Positive reactions were also obtained with sera of three of eleven patients with Hodgkin's disease, with five of the six foetal sera tested and with the four solubilized extracts of leukaemic cells that were tested. Negative results were obtained with twenty-two sera from healthy volunteers, with solubilized extracts of normal spleens and buffy coat and with haemolysed group A red cells, inactivated papain and prednisolone (Table 2). We have shown that solubilized extracts of rapidly growing established lymphoid cell lines failed to react with xenogeneic antisera raised against LAA and in addition whole cells of these lines did not absorb out leukaemic specificities (Viza, Phillips and Harris, unpublished). It is unlikely therefore that LAA are artefacts or that they are simply antigens common to all rapidly growing tissues. More sensitive techniques and stronger antisera, now being investigated may, however, detect more positive reactions and it is not yet clear to what extent quantitative and qualitative phenomena are involved.

Table 2 Reactivity of Absorbed Rabbit Antiserum (FXP) and Various Antigens

Antigen	No. of specimens tested		No. of positive reactions	
	DD	COE	DD	COE
Serum from patients	50	50	2	15
Soluble semi-purified leukaemic antigen (2 mg/ml.)	4	4	4	4
Foetal serum	6	6	5	5
Normal human serum	22	22	0	0
Sol. HL-A extracts from normal spleens (2.5 mg/ml.)	16	NT	0	NT
Soluble extract of normal buffy coat (2.5 mg/ml.)	1	NT	0	NT
Haemolysed group A red cells	NT	2	NT	0
Inactivated papain (10 mg/ml.)	4	2	0	0
Prednisolone (20 mg/ml.)	NT	1	NT	0

NT, Not tested; DD, double diffusion; COE, cross over electrophoresis.

The reactivity of xenogeneic antisera, prepared against solubilized extracts of AML cells, with sera obtained from some patients with other forms of leukaemia or with Hodgkin's disease is perhaps surprising. Common oncogenic viruses may be involved in producing LAA and it is possible that hitherto unsuspected aetiological heterogeneity may exist within the framework of current histological classification. Alternatively different agencies might open up similar biochemical pathways leading to "new" antigen formation. Thus our earlier results suggested that antigens common to leukaemia and embryonic extracts occur[5,6] and the results described here show that these may be found also in embryonic serum. Such leukaemo-embryonic antigens may be an expression, following malignant transformation, of genes which are partially or completely repressed in the normal adult genome and our observations provide an interesting analogy with those of Gold[13] and von Kleist and Burtin[14] who have described a carcino-embryonic antigen in human colonic tumours.

Modification of Hyperacute Rejection of Sheep Kidney Heterografts in the Dog using a Trypsin Inhibitor

WHEN the species barrier is crossed in organ transplantation, rejection is often hyperacute and immediate. Thus when a sheep kidney is perfused from the dog circulation, the blood flow through the kidney ceases in about 10 min and the transplanted organ increases in weight considerably. Platelet levels

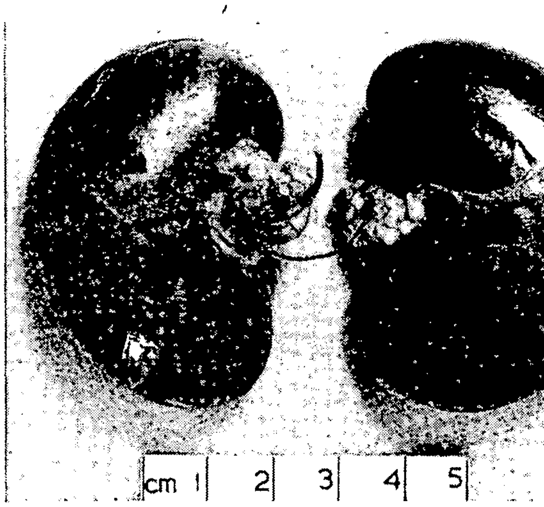

Fig. 1 Sheep kidney heterograft (right) after hyperacute rejection by the dog and its pair (left) showing less severe changes on rejection when trypsin inhibitor was present in the circulation.

and platelet stickiness measured in the sheep renal vein effluent and in the dog circulation reveal marked platelet trapping by the rejected organ. Those platelets that do emerge are not very sticky. The second of a pair of sheep kidneys connected to the same dog circulation after rejection of the first follows a similar pattern of rejection (Tables 1 and 2).

Table 1 Peak Flow, Duration of Perfusion and Weight Gain of Each of a Pair of Sheep Kidneys Perfused Sequentially from the same Dog Circulation

	Experiment	Peak flow (ml./min)	Duration of perfusion (min)	Weight gain (g)
(1)	First kidney	20	12	+5
	Second kidney	26	13	+7
(2)	First kidney	240	11	+5
	Second kidney	250	12	+5
(3)	First kidney	260	17	+5
	Second kidney	200	16	+5
(4)	First kidney	110	10	+5
	Second kidney	130	11	+5

Table 2 Platelet Levels and Stickiness from Each of a Pair of Sheep Kidneys Perfused Sequentially from the same Dog Circulation

Experiment	Dog systemic blood Platelets/mm³	Dog systemic blood Stickiness (%)	First kidney effluent Platelets/mm³	First kidney effluent Stickiness (%)	Second kidney effluent Platelets/mm³	Second kidney effluent Stickiness (%)
1	240,000	55	51,500	5.5		
	223,000	65			46,000	2.6
2	272,000	65	60,000	3.8		
	287,000	44			58,000	4.7

4	190,000	45	44,000	2.3		
	194,000	58			48,000	2.6

Because of the reproducible pattern of rejection of pairs of sequentially transplanted sheep kidneys into the same dog circulation, the system can be used as a model to study the effect on hyperacute rejection of an agent present during perfusion of the second kidney and not during the first. Dogs (20 kg) were injected intravenously with 25,000 U of a trypsin inhibitor, 'Trasylol', to prevent the release of the vasoactive local tissue hormone bradykinin from the α_2 globulins of the dog blood; and the role that this hormone plays in the processes of hyperacute rejection was studied. The injection of a trypsin-inhibitor into the dog circulation had no effect by itself on platelet levels or stickiness (Table 3).

The recipient dogs were anaesthetized with intravenous thiopentone and maintained with halothane, nitrous oxide and oxygen through an endotracheal tube. The kidneys were removed quickly from sheep anaesthetized with thiopentone; heparinized isotonic saline was injected into the renal artery to prevent blood clotting and the kidneys were weighed and cooled on ice. Connexion was made by short siliconized 'Portex' tubes from dog common carotid artery into sheep renal artery and the renal vein effluent blood flow was measured by drop count. The time taken for perfusion to cease was recorded and the kidney re-weighed after disconnexion. Serial platelet counts were done in the dog circulating blood and in the sheep renal vein effluent, and platelet stickiness was measured by the method of Hellem[1].

The results show a marked effect on the pattern of rejection of the second kidney after introduction of trypsin inhibitor. The time before perfusion ceased was prolonged, the peak flow increased, the weight gain of the transplanted kidney was not so prominent and the appearance of the organ was less engorged (Fig. 1). Platelet counts in the emergent renal blood flow did not drop so much as from the first kidney, revealing that the second kidney under the influence of trypsin inhibitor was not trapping platelets as powerfully as the untreated first kidney. The platelets that emerged after perfusing the second kidney

Table 3 Effect of Intravenous Trypsin Inhibitor on Platelet Levels and Stickiness in Dogs

	Platelets/mm³	Stickiness (%)
Dog 1	210,200	29

	311,200	62			80,200	32

were of undiminished stickiness compared with the dog circulation (Tables 4 and 5).

The finding that the introduction of 'Trasylol', which prevents the release of bradykinin, delays the rejection of sheep kidney heterografts by the dog suggests that this vasoactive hormone is one mediator in the changes that take place in the florid and immediate hyperacute rejection seen when species barriers are crossed in transplantation.

We thank Dr H. B. Allen and Mr J. Dixon of Bayer Laboratories for 'Trasylol'.

Presence of EBV Antibodies in Sera from Wild Chimpanzees

THE marked geographical distribution of Burkitt's lymphoma in Africa has suggested that the aetiological agent is infectious and arthropod-borne[1,2]. A herpes-like virus, first described by Epstein *et al.*[3], has been associated consistently with lymphoid cells cultured from cases of Burkitt's lymphoma[4]. Furthermore, immunofluorescent tests, using Burkitt lymphoma cells, have demonstrated antibodies against this Epstein-Barr virus (EBV) in all sera from patients with Burkitt's lymphoma and in sera from many healthy African controls living in the endemic regions[5-6]. These observations indicate that EBV infection is widespread, and suggest that the virus in some individuals might be involved in the development of Burkitt's tumour.

In spite of the several epidemiological studies of the disease[7-9], the manner by which an infectious agent might pass from man to man has not been determined. Because many Africans are affected each year, Williams[10] proposed that some animal reservoir might account for the continual presence of the disease and that it could be passed to man by insects. The areas of Africa in which the lymphoma is common overlap those in which malaria is prevalent[11-12] but no EBV has been isolated from mosquitoes or other insects[13]. Banfield[14] has reported that whole cells from reticulocyte tumours of hamsters can be carried by mosquitoes, but no evidence of this kind of transmission, such as the presence of female cells in male patients, has been found in cases of Burkitt's lymphoma.

Gerber and Birch[15] found that chimpanzees had the highest frequency and titres of antibodies to EBV, but that sera from Old World primates (baboons and monkeys) also reacted with EBV antigen. In contrast, none of the sera from nine species of lower mammals, including horse, cow and pig, had antibodies to the antigen. Landon *et al.*[16] have found a herpes-like virus similar to EBV in cultivated leucocytes from chimpanzees. The animals had antibodies which reacted with this agent in their cells and with the EBV present in cultured human Burkitt lymphoma cells. These data strongly suggest that wild primates, particularly the chimpanzee, might be the reservoir for the spread of EBV infection by insects to man.

All the primates studied so far had been exposed to man for sufficient periods of time to become infected with the virus. It was important therefore to investigate animals that had not been in contact with humans. Rhesus monkeys tested within 4 days after capture had been found to have EBV antibody[17], but these animals are known to have contact with man. The chimpanzee, on the other hand, was ideal for this purpose since it fears man, has no natural contact with him and seems to be highly susceptible to the herpes-like virus.

A preliminary study was conducted in the Budango Forest in Western Uganda, an area which is situated within the "lymphoma belt" and which contains a large chimpanzee population. The chimpanzees were captured by immobilizing them with darts containing an anaesthetic agent. Blood samples were taken immediately, and the animals on awakening were allowed to return to the jungle.

Ketamine hydrochloride ('Ketalar'), a relatively new anaesthetic agent (provided in powder form by Parke, Davis and Company, Chicago), was dissolved in water (*p*H adjusted to 6.8 with sodium hydroxide) at a concentration of 200 mg/ml. This drug has been shown to induce muscle immobilization without adverse effects on the autonomic or cardiopulmonary systems[18]. Moreover, it was chosen because at relatively low doses (10 mg/ml.), the onset of action in monkeys occurs within 5 min and recovery from anaesthesia takes only 30 min[19]. And because it is without side effects in other primates, it was considered superior to the more commonly used immobilizing agent, phenylcyclidine hydrochloride ('Sernylan'), in spite of the lack of a trial with chimpanzees. The drug was placed in darts of varying sizes which were fired by the Cap Shur gun designed by Palmer Associates, Georgia. In the Budango Forest the chimpanzees feed at the top of fig trees at a distance of 80–100 feet. They were approached by foot with care but their keen senses made them extremely difficult to catch. In a week, three chimpanzees, each from a different chimpanzee colony, were successfully bled; the anaesthetic agent was as effective as it is in monkeys and no change in respiration or heart rate was noted during immobilization.

The P3 (Jijoye) Burkitt lymphoma cell line[20] and the LE-7 chimpanzee lymphocyte line[16] were used. Both lines contain a herpes-like virus in 3–5% of the cells. Fluorescent antibody (FA) testing was conducted as previously described[5,21] using fluorescent-labelled goat anti-human globulin and anti-monkey globulin. Both react well with chimpanzee globulin; the anti-human globulin is somewhat more efficient.

Table 1 Wild Chimpanzee Sera Anti-HLV Titres

			Anti-globulin titres	
Sera	Age	Sex	Goat anti-human	Goat anti-monkey
(*A*) Antigen: human HLV (Jijoye cell line)				
4419	A	M	1/160	1/40
4420	I	M	1/40	1/10
4421	A	F	Negative	Negative
(*B*) Antigen: chimpanzee HLV (LE-7 cell line)				
4419			1/160	1/40
4420			1/5	Negative
4421			Negative	Negative

Chimpanzee sera were incubated with either human or chimpanzee cell lines. After 1/ h the sera were removed by washing twice with phosphate-buffered saline and the cells were allowed to react for 1 h with fluorescent-labelled goat anti-human or anti-monkey antisera (both are known to react with chimpanzee globulin). A, Adult; I, 4 month old infant; HLV, Herpes-like virus.

As noted in Table 1, two of three sera obtained from the wild chimpanzees reacted with both human and chimpanzee lymphocyte cells. The FA staining resembled that seen with human anti-EBV sera[4,5,21] and involved 3–5% of the cells. Sera 4419 obtained from a 200 pound male chimpanzee gave comparable titres in both chimpanzee and human cells. Serum 4420, on the other hand, reacted with a somewhat greater titre against the herpes-like virus in the Jijoye line than against the herpes-like virus in the LE-7 cells. This result contrasts with reports[22] of a preferential staining of the LE-7 chimpanzee cell line by chimpanzee sera.

These data on blood specimens from three different chimpanzee groups which had not been in contact with humans demonstrate that the wild chimpanzee has been infected by EBV or a very similar herpes-like virus. Whether these antibodies are specific for the EBV associated with Burkitt's lymphoma, as implied by the serum of 4420, or whether they represent a cross-reaction with related chimpanzee virus(es) is not yet known. The presence of these antibodies suggests that wild chimpanzees, and perhaps other primates in the forest within the lymphoma belt, could be the reservoir for an arthropod-spread of EB virus infection to man.

These studies were supported by a grant in aid from the Kresge and Strasburger Foundations and by a grant from the US National Institutes of Health.

Possible Structural and Functional Differences of the Two Conformers of Myoglobin-like Molecules with Respect to the Haem-Haem Interaction

IN spite of the significance of myoglobin (Mb)[1] the details of its functional mechanism remain unknown. This is probably due, first, to the lack of physical models for the oxygenation mechanism[2] and, second, to the scant knowledge of the properties of the different conformations of Mb in the native state.

The temperature dependence of a number of molecular parameters in the range 0°–50° C is anomalous, and can be explained by postulating the existence of two conformational isomeres in a temperature-dependent equilibrium[3]. Such a consideration of the data on the nuclear magnetic relaxation (NMR: the rate of spin-lattice relaxation, $1/T_1$, of water protons) indicates the displacement of the first hydration shell Mb neighbouring or of the haem iron atom in the high-temperature conformer Mb(B) and its withdrawal from the haem by about 1.0–1.6 Å in the low temperature form Mb(A)[4,5]. It follows from the protein structure[6] that this must arise from a shift in the *F*-helical chain. Fig. 1 shows the relative change of $1/T_1$ with temperature for dolphin met-Mb in aqueous solution (black squares). The (A)⇄(B) transition elicits (or is perhaps provoked by) a change in the nature of the hydration shell. The conformers differ in stability by not more than 1–2 kcalories/mol[3].

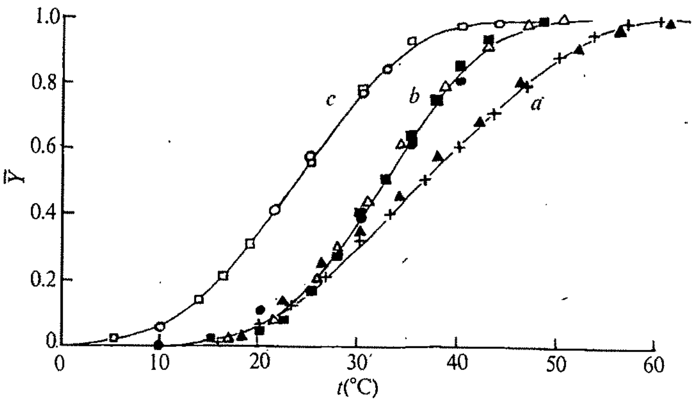

Fig. 1 Temperature-dependence of fractional changes ($\bar{Y}$) $\bar{Y}=\frac{Yt-Y_{min}}{Y_{max}-Y_{min}}$ for some physico-chemical parameters ($Y=1/T_1$, $E_{a,r}$, ε_{245}, C_p and $p/_{\frac{1}{2}O_2}$) of ferri-MbCN (curve *a*), met- and oxy-Mb (curve *b*) from some homoeotherms and of ferri(met)-Hb-s from some poikilotherms (curve *c*).

Our recent investigations of sperm whale met-Mb modified by iminoxyl spin-labels (Yu, D., Akhmedover, B. P. A., and Lichtenstein, G. I., unpublished) (three iminoxyl spins per molecule of protein, probably attached to *his 48*, *his 81* and *his 119*) showed a change in activation energy ($E_{a,r} \sim d(\ln\upsilon)/d(1/T)$) of the label rotation on heating. This parameter follows the same curve as the NMR (Fig. 1, open triangles, $Y=E_{a,r}$). The label rotation in Mb(A) is more restricted than in Mb(B). The conformational transition (A)⇄(B) probably involves *CD*, *EF* and *GH* regions of Mb[6].

On heating the sperm-whale ferri-MbCN solution (*p*H 11.0–11.5), the absorbance changes at 245 nm in a biphasic manner, with $\Delta\varepsilon_m$ of 10^4 and 2×10^4 for the two steps. The change reflects ionization of tyrosine on heating. The absence of the first step when dolphin ferri-MbCN is heated (*try HC3→phe*[7]) indicates that during the transition to Mb(B), changes also occur in the *C*-terminal region of the molecule. The concurrent change in ε_{280} reflects the true heat denaturation of the protein. The relative change with temperature of ε_{245} is shown in Fig. 1 (crosses, $Y=\varepsilon_{245}$).

Microcalorimetric studies of sperm whale ferri-MbCN have demonstrated a change in heat capacity (C_p) in the range 35° ± 18° C (ref. 8). This is effectively a phase transition of the second type and also indicates changes in the hydration shell of the protein (change of molar volume as a result of changes of the free volume of the solvent[9], and the increase in freedom of solvent at the surface of Mb(B)). Apparently, the transition (A)⇄(B) encompasses all the surface of the molecule (Fig. 1, black triangles, $Y=C_p$).

Partial oxygen pressure at half-saturation[10], $P_{\frac{1}{2}O_2}$, that is the affinity of Mb for oxygen, shows a rise with temperature, the course of which coincides with the conformational equilibrium (A)⇄(B) (Fig. 1, black circles, $Y=p_{\frac{1}{2}O_2}$). A complete description of the process demands, first, that the conformational isomers differ in oxygen affinity; second, that of Mb(B) being less than that of Mb(A); and third, that the predenaturation transition is related to the oxygenation function.

Analogous parameters for some poikilotherms (Fig. 1, open squares, $Y=1/T_1$ for lamprey haemoglobin (Hb)[11]; open circles, $Y=p_{\frac{1}{2}O_2}$ for frog Hb[12]) have similar profiles shifted, however, to a lower temperature. There is probably a deeper causal connexion between the physiological temperature of each animal species and the temperature of the conformational transition ($T=T_{tr}$ when $\bar{Y}=0.5$) with which it coincides. The relation between the optimum of conformational stability for the proteins of a given organism and the physiological temperature has been the subject of many investigations[13].

A shift of the F-helical chain towards the haem is equivalent to a "push in" of proximal *his F8* (the fifth ligand of the iron atom). This should lead to a decrease in binding strength of the sixth (distal) ligand, particularly if the latter, like oxygen, is principally bound by a π-dative bond—an effect not realizable in small molecules and denoted here a "conformational trans-effect" (see also Lumry[14,15]). A shift of the bonding nitrogen atom of *his F8* by as little as 0.2 Å results in such a strong tetragonal distortion of the ligand field (a change in the electronic population of the higher orbitals, mainly those with ε_g-symmetry) that the binding strength of the sixth ligand may decrease by 5–8 kcalories/ml. Naturally, the inverse should also apply, the binding of the sixth ligand leading to a displacement of the fifth with a corresponding displacement of the (A)$\rightleftarrows$(B) equilibrium. The shift of the F-helix might cause a small concurrent separation of the *E*(*D*) and *C*(*B*)-helical chains, resulting from the absence of cavities in that part of the molecule. Thus one can expect the conformers to differ in structurally small but functionally important details[3].

The (A)$\rightleftarrows$(B) equilibrium may thus function as a control mechanism for the oxygen affinity of Mb (a simple analogue for the conformational control of the affinity of enzyme for substrate). The position of the equilibrium, and still more the activation parameters of the transition, must be affected by the presence or absence of the ligand molecule, as well as its nature, and by intermolecular protein interactions. The latter are probably the cause of "freezing" of four Mb-like subunits of deoxy-Hb in the (B) conformation. If the O_2 bond to the first subunit leads to a change into form (A) and a decrease in interaction energy between other subunits[17], the structure "melts" and the remaining subunits enter the more reactive state (A). The concept of such a conformation-dependent haem-haem interaction in Hb is supported by a number of lines of evidence.

These studies were carried out in collaboration with the laboratories of P. L. Privalov (Institute of Protein Research, Academy of Sciences, USSR), G. I. Lichtenstein (Institute of Chemical Physics, Academy of Sciences, USSR) and A. Derzhanski (Institute of Physics, Bulgarian Academy of Sciences).

Non-coordinated Accumulation and Synthesis of 5S Ribonucleic Acid by Ovaries of *Xenopus laevis*

ALTHOUGH the primary structure of 5S RNA from a number of organisms[1–3] is known and although it is clear that the attachment of a 5S RNA molecule is necessary if ribosomes are to be effective in protein synthesis, the precise role of these molecules is unknown. Molecules of 5S RNA are non-covalently attached to the large ribosomal subunit[4–7] and can be removed only by procedures which change the conformation of the subunit[8] and, in bacterial systems at least, they can be reunited to give particles which are effective in protein synthesis[9]. Studies of 5S RNA in HeLa cells have shown that, in the cytoplasm, 5S RNA molecules are found only in association with ribosomes, but that as much as a fifth of all the 5S RNA in a cell is to be found in the nucleus, much of it in the nucleolus[10] in association with particles which seem to be precursors of ribosomes[7]. In the circumstances, it would be natural to expect that the three RNA molecules found in ribosomes—5S RNA, 18S RNA and 28S RNA—would be synthesized in equal numbers, and there is indeed some evidence of coordinated synthesis from the development of *Xenopus laevis*[6–11]. During the early stages of oogenesis in the same organism, however, we have now found that 5S RNA molecules are formed in great excess.

Table 1 Molar Ratio of 5S rRNA, 18 and 28S rRNA and 4S RNA in *Xenopus* Liver and Ovary

Ovary	5S/18 and 28S	4S/18 and 28S	4S/5S
Late vitellogenesis	7.5	5.4	0.72
Late vitellogenesis	10.4	6.1	0.59
Late previtellogenesis	110.0	254.0	2.30
Early previtellogenesis	74.0	92.0	1.24
Liver	0.88–1.21	19.5–26.3	20.0–30.0

Total RNA from ovaries of different ages was prepared and analysed on 'Sephadex G100' columns as described in Fig. 2. The total absorbance at 260 nm was calculated for each fraction. It is assumed that the absorbance of the void fraction is due entirely to 18 and 28S rRNA. The molar ratios were calculated assuming a combined molecular weight of 2.2×10^6 for 18 and 28S RNA, and of 40,000 for 5S rRNA and 30,000 for 4S RNA.

RNA was isolated from *Xenopus laevis* ovaries at various stages of development and separated on 'Sephadex G100' columns into three fractions, the void fraction containing the 18S and 28S rRNA, the 5S and the 4S fractions. (For comparison, RNA from *Xenopus* liver has been separated in the same way.) The results (Table 1) suggest that previtellogenic ovaries accumulate 5S and 4S RNA in great excess, but that 18S and 28S rRNA is accumulated during vitellogenesis. From the molar ratios obtained in several experiments, it seems that enough 5S RNA is accumulated in previtellogenesis to allow a hundred-fold increase in ribosome content during vitellogenesis without the need for further 5S synthesis.

Two interpretations of these results are possible—either 5S RNA is synthesized in excess of 18S and 28S rRNA or that

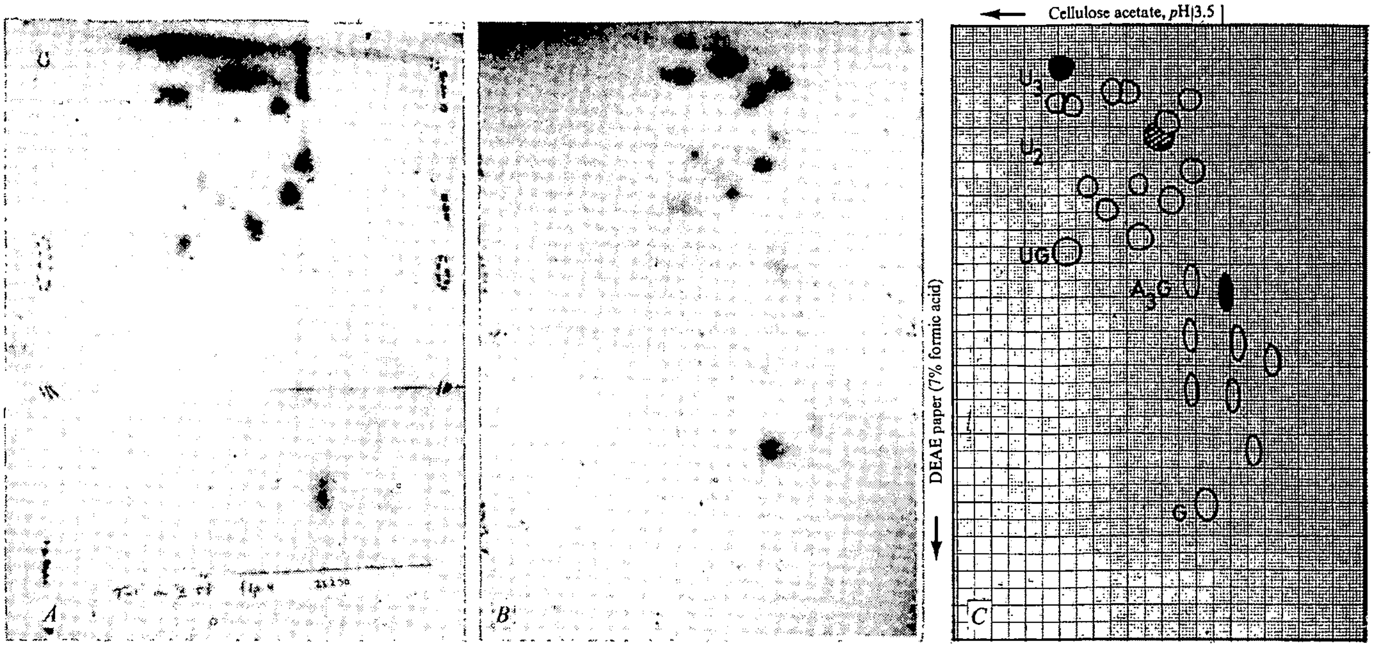

Fig. 1 10 μg 5S RNA (30,000 d.p.m. ^{32}P/μg) isolated[19] from *Xenopus* kidney cells grown in continuous cell culture, and 20 μg of *Xenopus* previtellogenic ovary 5S RNA (10,000 d.p.m. ^{32}P/μg) prepared by extraction of total RNA from ovaries incubated in 2/3 Eagle's medium plus 10% calf serum with 2.5 mCi/ml. ^{32}P for 2 days and separation by G100 chromatography as described in the legend to Fig. 2, were hydrolysed with T_1 ribonuclease[20] (Sankyo). The oligonucleotide fragments were separated by a two dimensional electrophoresis method[14]. *A, Xenopus* kidney cell ribosome 5S RNA; *B, Xenopus* previtellogenic ovary 5S RNA. The diagram (*C*) indicates (filled circles) oligonucleotides present in *A* but absent in *B*, and (hatched circle) oligonucleotides present in *B* but absent in *A*. Open circles are oligonucleotides common to both *A* and *B*.

synthesis is coordinated but that the 5S RNA species is more stable than the other two. We have therefore carried out an experiment to test whether the synthesis of the two species is coordinated. Ovaries at various stages of development were labelled with ^3H-uridine in culture for one day and total RNA from a post-mitochondrial supernatant was isolated and mixed with ^{14}C-labelled RNA prepared from 80S ribosomes isolated from late vitellogenic ovaries incubated with ^{14}C-uridine for six days. After separation of RNA on a sucrose gradient and by G100 chromatography, the $^3H/^{14}C$ ratios were computed and normalized with respect to 28S rRNA in sucrose gradients and to the void fraction in the 'Sephadex G100' columns. Table 2 shows that, as expected, 18S rRNA is synthesized coordinately with 28S rRNA, but that 5S RNA is synthesized in fifteen to twenty-fold molar excess of 18S and 28S rRNA in early previtellogenic stages and that this ratio decreases to a three to four-fold molar excess at later stages. These results are compatible with the non-coordinate synthesis hypothesis, but incompatible with the non-coordinate degradation hypothesis unless the half life of the 18S and 28S rRNA is less than 1–2 h. They do not exclude the possibility that 5S RNA is synthesized coordinately with the 40S rRNA precursor[13] which is degraded without maturing into 18 and 28S RNA.

To show that the 5S RNA accumulated in previtellogenic oocytes is similar if not identical to the 5S RNA from *Xenopus* kidney cell ribosomes, T_1 ribonuclease digests were obtained from each molecule and analysed by two dimensional electrophoresis[14]. Fig. 1 shows that the two oligonucleotide maps are

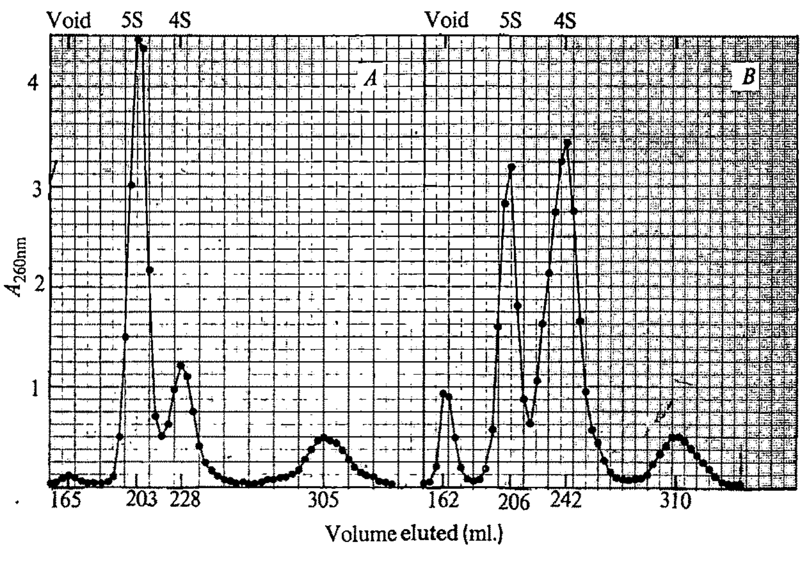

Fig. 2 Pooled previtellogenic ovaries were homogenized in 0.25 M sucrose, 50 mM Tris HCl (*p*H 7.6), 35 mM KCl and 1.5 mM $MgCl_2$ and centrifuged at 11,000 r.p.m. for 15 min at 0° C in a Sorvall RC2° centrifuge. The supernatant was layered over 50 ml. 10–50% linear sucrose gradients in 50 mM Tris HCl (*p*H 7.6), 35 mM KCl and 1.5 mM $MgCl_2$ and centrifuged at 25,000 r.p.m. for 18 h at 2° C in a Beckman SW 25.2 rotor. The optical density was monitored at 254 nm using an Isco density gradient fractionator and the fractions corresponding to the peaks at the top and 42S region were collected, precipitated with one volume of ethanol and recovered by centrifugation. The RNA was extracted from the pellets by the method of Kirby[18]. After recovery by alcohol precipitation the RNA was dissolved in 2 ml. 10 mM sodium acetate (*p*H 5.0) and 0.1 mM EDTA and loaded on 200×1.9 cm G100 'Sephadex' columns in the same buffer. The columns, at room temperature, were eluted at 6.5–7.5 ml./h and fractions were collected every 30 min. The absorbance at 260 nm was read for each fraction in a 10 mm light path cell using a Unicam 'SP500' spectrophotometer. *A*, RNA from the top of the gradient, 104 A_{260nm} units added, recovery 84%; *B*, RNA from the 42S particle, 168 A_{260nm} units added, 95% recovery. The elution buffer contained 0.01 mM sodium azide and was treated with 0.1% diethylpyrocarbonate at 60° C for 4 h before use.

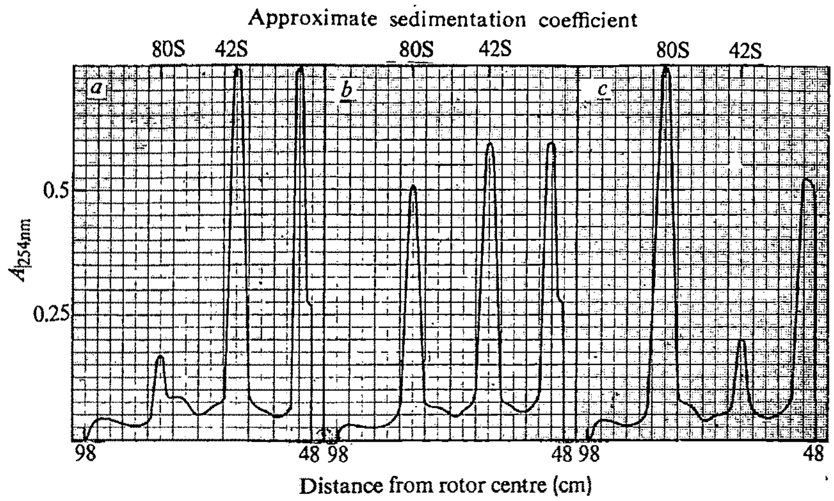

Fig. 3 Ovaries at three stages of development, (*a*) previtellogenic, (*b*) beginning of vitellogenesis and (*c*) mid vitellogenesis, were homogenized in 0.25 M sucrose, 50 mM Tris HCl (*p*H 7.6), 50 mM KCl and 1.5 mM $MgCl_2$ and centrifuged at 20,000 r.p.m. for 15 min at 0° C in a Sorvall RC2B. Aliquots of the supernatant fraction were layered on 5 ml. 10–30% sucrose gradients in the same buffer and centrifuged for 4 h at 39,000 r.p.m. at 10° C in a Spinco 'SW39' rotor. The absorbance at 254 nm was monitored continuously by an Isco density gradient fractionator.

very similar and the nucleotide compositions determined in sixteen of the twenty-three spots after elution and alkaline hydrolysis were identical. In most cases the position of a spot and its nucleotide composition give an unequivocal identification of the oligonucleotide sequence. The relative amounts of the oligonucleotides of the two RNA species were also found to be similar.

In the ovary 5S RNA, two spots in the kidney cell ribosomal 5S RNA map, one in the U_3 isoplith and the other near A_3G, are present in very small amounts and there may be an extra spot in the U_2 isoplith. Although these results are tentative, it is possible that secondary structure effects will render regions of the molecules less accessible to the nuclease, thus altering the relative proportions of particular spots. It is also possible that the base sequence of the oocyte 5S RNA is modified when it enters the ribosome.

The exact sequence relationship between the oocyte 5S RNA and 5S rRNA cannot be determined until the complete sequence is known, but it is sufficient at present to note that the oligonucleotide maps are extremely similar, and therefore that the ovary 5S RNA is very closely related to kidney cell 5S rRNA.

Although it has been shown[15] that the cytoplasm of previtellogenic oocytes is full of RNA it is not possible to observe typical ribosomes by electron microscopy of thin sections. Furthermore, it has been possible to demonstrate (Fig. 3) the existence of a ribonucleoprotein (RNP) particle sedimenting at 42S in the post-mitochondrial supernatant from an immature ovary. The 42S RNP is not a small ribosome subunit since in EDTA it does not cosediment with the small ribosome subunit, and in 0.5 M KCl it is converted into material sedimenting at the top of the gradient. The RNA isolated from the 42S material and from the top fraction of such gradients contains both 5S and 4S components (Fig. 2) but the relative amounts of each are different. Since labelled 5S and 4S RNA added before homogenization do not enter the 42S particle, one might infer that it is not an unspecific artefact of homogenization.

Table 2 Normalized Ratios of the Test for Coordinate Synthesis of Ribosomal RNAs by Immature *Xenopus* Ovaries

Normalized ratios					
Sucrose gradients			'Sephadex G100' columns		
28S	18S	4+5S	Void	5S	4S
1.00	0.90	12.05	1.00	16.4	38.20
1.00	1.12	15.60	1.00	21.95	51.80
1.00	0.96	5.41	1.00	4.55	22.30
1.00	0.91	4.60	1.00	5.04	15.30
1.00	0.84	2.19	1.00	4.44	11.45
1.00	0.96	2.58	1.00	3.19	13.87

After incubation in 2/3 Eagle's medium plus 10% calf serum with 200 µCi/ml. 5^3H-uridine for 1 day at 20° C, RNA was prepared from the post-mitochondrial supernatants of ovaries at different stages of growth. 1 and 2 represent pooled previtellogenic ovaries, 3, 4, 5 and 6 are duplicates from different early vitellogenic ovaries. The ^3H-labelled RNA was mixed with ^{14}C-RNA prepared from 80S ribosomes derived from late vitellogenic ovaries incubated in $2^{14}C$ uridine (2 µCi/ml.) for 6 days. The mixed RNA preparations were separated on sucrose gradients and G100 columns, fractions collected, precipitated with TCA, washed and counted in a toluene-PPO-POPOP mixture using a Beckman LS 200 liquid scintillation counter. The $^3H/^{14}C$ ratios were computed by the ^{14}C channels ratio method. The average $^3H/^{14}C$ ratios for the peak fractions were taken and normalized in the case of the sucrose gradients to the 28S RNA fraction and in the case of the 'Sephadex G100' columns to the void volume fraction, assumed to be entirely 18 and 28S RNA.

It would seem that a substantial proportion (60%) of the low molecular weight RNA of the immature oocyte is present in a unique form of cytoplasmic ribonucleoprotein particle. It is unique for several reasons: first, it is not usual for 4S RNA to enter such large RNP complexes; second, there is no previous report of a cytoplasmic particle other than a ribosomal large subunit containing 5S rRNA; third, it is shown to contain two major proteins by acrylamide gel electrophoresis in 6 M urea at *p*H 4.5, and proteins with similar mobilities are present in the top fraction of a gradient in only small amounts. Finally, knowing that the amounts of 18S and 28S rRNA and 5S rRNA change during oogenesis (Table 1), it is predicted that the relative amounts of the 42S material and 80S ribosomes also change during oogenesis (Fig. 3).

In the normal diploid *Xenopus* cell 5S rRNA genes are in twenty-five to thirty-fold excess of 18S and 28S rRNA genes[11], while in the oocyte 18S and 28S rRNA genes are in forty-fold excess of 5S rRNA genes, since, unlike the 5S genes[12], the 18S and 28S genes are amplified[16]. There is evidence[17], in the case of the *Xenopus* oocyte, that the 18S and 28S cistrons are maximally packed with polymerase, and if one assumes the same is true for the 5S rRNA cistrons, and that the nucleotide step time is the same for both sets of genes, then the oocyte is capable of producing forty times more 18S and 28S rRNA than 5S rRNA in a given time, which clearly makes 5S rRNA limiting for ribosome assembly. It would seem therefore that before the maximum rates of 18S and 28S rRNA synthesis are attained a large store of 5S rRNA molecules is required.

I thank the Medical Research Council for support. Most of this work was performed at the National Institute for Medical Research, Mill Hill, London. I thank Dr Robert Williamson and Mrs T. McShane for preparing oligonucleotide maps and Dr Max Birnstiel for help and criticism.

Lead Absorption from the Intestine in Newborn Rats

THE tendency of the young of a given species to be more prone to lead poisoning than the adult has been observed by several authors[1], and we have investigated whether one of the reasons for this could be an increased absorption of lead from the intestine during an early stage of life.

We used 5–7 day old rats which were artificially fed for 8 h with cow's milk to which $CaCl_2$ and KH_2PO_4 were added to adjust the calcium and phosphate content to the normal level of rat's milk[2]. The technique was essentially that used before[3,4]. Carrier-free lead-203 was added to the milk and each animal received about 2 μCi. At the end of the artificial feeding period the young were returned to their mothers where they stayed until they were killed 40 and 80 h after the beginning of the experiments. The radioactivity of lead-203 was determined in the whole body before and after removal of the gastrointestinal tract in a two sodium iodine crystal assembly. Retention was expressed as percentage of the ingested dose.

Table 1 reveals a high retention of about 55% of lead-203 at both intervals. The lower value in the carcass at 40 h indicates that some radioactive lead was still present in the gastrointestinal tract at the earlier time interval. This fraction becomes absorbed after 80 h, as indicated by the higher value in the carcass and by the same retention figure obtained in the whole body and carcass at the later interval.

Table 1 Absorption of Radioactive Lead from the Intestine in Artificially Fed 5–7 Day Old Rats

		Lead-203 in the body % ingested dose	
No. of rats	Time of death (h)	With intestinal tract	Without intestinal tract
12	40	55.80±2.3	41.86±1.85
17	80	57.41±1.71	53.37±1.77

Lead-203, $CaCl_2$ and KH_2PO_4 were added to cow's milk which was fed to rats by means of a dropper during 8 h; each rat received an average of seventeen drops (0.45 ml.); each figure represents the arithmetic means and the standard error of the mean.

The principal finding, however, remains the very high absorption of lead from the intestine of newborn rats. Adult rats (4 month old females) retain within the same time interval only about 1% of the oral dose of radioactive lead[5]. If we compare these results with those obtained in our previous experiments on absorption of calcium and strontium in newborn rats with almost the same experimental technique (70–75% absorption for ^{47}Ca and ^{85}Sr after 40 h), it is seen that the absorption of lead is only 25% lower than the very high absorption of calcium and strontium characteristic for this age group. If we assume that the percentage of intestinal lead absorption is not influenced by dose[6], we could expect much more lead to be absorbed from the intestine in the young than generally supposed. If these values are expressed per kilogram body weight, the difference in the amount of lead absorbed per unit weight in young and adults would be even greater. We therefore consider that this factor should be taken into consideration when interpreting the well known differences in the symptoms of lead poisoning in adults and young children. Our results could also be important for determining criteria for human safety from contamination of the ambient atmosphere with lead, which might have to be corrected for young children when compared with adult values.

Spanish Moss, a Sensor for Lead

THE heavy metal content of various plants has been related to sources of air pollution[1]. Trees growing near London, England, were found to contain more lead than those growing in the country[2]. Grass near a highway was found to contain more lead than grass further away[3]. These studies involved root type plants that obtain their nourishment from the soil.

More useful information can be obtained from measurements of heavy metals in epiphytes, which derive all their nutrients from the air. They may concentrate certain elements in a manner analogous to the concentration of mercury in tuna fish and DDT in penguins. Ruhling and Tyler reported that some mosses are good indicators for lead accumulation[4]. Tyler has shown that carpet-forming mosses may also be used to measure the deposition of other heavy metals (unpublished results of G. Tyler).

We wish to report some preliminary measurements made with Spanish moss (*Tillandsia usneoides*), an epiphyte and a member of the family Bromiliaceae, which promises to prove useful as a monitor of lead and other heavy metals in the atmosphere. Wherry and Buchanan analysed three samples of the ash of Spanish moss and found them to contain much soda, potash, ferric oxide, sulphur, chlorine, and silica[5]. They found a sample from the sea coast contained more chlorine than an inland sample, suggesting a higher level of atmospheric salt near the coast due to sea spray. They considered that the scales which cover the moss hold capillary water from which the plant absorbs nutrients. They found little systematic difference between washed and unwashed samples indicating that adherent dust had a negligible effect on their results. Wherry and Capen reported additional measurements of Spanish moss and Ball-moss (*Tillandsia recurvata* L.)[6].

Table 1 Lead Content in Moss Samples

Sample location	Description of sample location	Collection date	Lead content (%) (dry basis) Unwashed samples	Washed samples In sample of moss	Washed samples In wash solution
A	Adjacent to heavily travelled four-lane highway	Feb. 19, 1971	0.067		
B	On residential street along the shore of a lake in Baton Rouge	Feb. 24, 1971	0.026		
C	0.8 mile from a secondary paved highway	March 23, 1971	0.0051		
D	Adjacent to the secondary paved highway from which sample C was obtained	March 23, 1971	0.011	0.009	0.003
E	0.1 mile from an unpaved road	March 23, 1971	0.0052	Not determined	0.0005
F	Adjacent to heavily travelled four-lane highway in Baton Rouge	March 23, 1971	0.085	0.0966	0.0434
G	On residential street along the shore of a lake in Baton Rouge	March 23, 1971	0.028	0.0154	0.0071
H	0.3 mile from a secondary paved road	March 23, 1971	0.0052		

Using atomic absorption spectrometry, we have measured the lead content of samples of Spanish moss from various locations and found it extremely high (Table 1). There must be a mechanism which concentrates this lead. Samples A and F which contain the most lead were collected from the busiest highways, the next highest lead content was in samples from Baton Rouge, and the next highest on a secondary road parallel with Bayou Grosse Tete. Sample C, 0.8 mile from this road, contained approximately half as much lead as the road-side sample. Samples C, E and H, all of which were most distant from well travelled roads, had the lowest lead content.

Some of the samples were washed with an ammonium acetate solution to determine whether the lead was surficial or in the tissues. Appreciable amounts of lead were removed from samples D, F and G, but little was removed from sample E. The total amount of lead in the wash solution from sample F and the washed moss amounts to 0.14% which was more than that in the unwashed sample, possibly because of sampling technique or variability within the sample. Consistent lead values in samples remote from roads and the ineffectiveness of washing one of these samples suggest that for these samples the lead may be in the tissues of the moss.

The abundance of Spanish moss in the Gulf Coast provides the opportunity of establishing gradients from line and point sources of pollutants.

We thank Dr James Robinson, Dr Arun Shandrikar and Mr Kenneth Reiszner for advice and Dr Philip West for the use of laboratory equipment.

Recovery from Zoxazolamine Paralysis and Metabolism *in vitro* of Zoxazolamine in Ageing Mice

SENESCENCE has been viewed as the progressive loss or diminution of the ability of an organism to regulate or maintain obligatory levels of activity of its various enzymes[1–8]. The primary reason(s) for this age-dependent loss in regulatory capacity is unknown. The study of the biochemical parameters associated with senescence has been hampered by the inability to correlate a decreased functional capacity for the organism with a loss or diminution of functional capacity at the molecular level.

The hepatic microsomal enzyme system may prove useful in overcoming this obstacle. Clearly the principal function of this enzyme system is not the metabolism of drugs or other unnatural substrates which have been used to study it, but the intermediary metabolism of fatty acids and steroid hormones[9]. The system will, however, accept various substrates, use of which has made possible its separation into a variety of components[10]. All these components can be studied individually or *in toto* as a function of age.

Here we show that the ability of mice to recover from paralysis induced by zoxazolamine (2-amino-5-chlorobenzoxazole, 'Flexin', gift of Mr John Kleis, McNeil Laboratories, Inc., Fort Washington, Pennsylvania) decreases with advancing age. Furthermore, this overtly demonstrable decrease in the capacity of the organism to recover is paralleled by a decrease in the ability of the hepatic microsomal enzyme system to metabolize the drug *in vitro*.

C57BL/6J male mice of different ages were injected with zoxazolamine. The mean recovery time of young mice from drug paralysis was found to be approximately half that of 900 day old mice (Table 1), which agrees with similar studies performed *in vivo* with rats of different ages[11]. These results suggested that the age-related difference in recovery time from zoxazolamine paralysis reflect differences in the rate of metabolism of zoxazolamine, although it was possible that the observed differences reflect an age-dependent difference in the rate of clearance of the drug from affected tissues. Liver homogenates were therefore prepared from individual mice of different ages and assayed *in vitro* for zoxazolamine hydroxylase activity[12,13]. The mean rate of metabolism of zoxazolamine *in vitro* by mouse liver whole homogenate decreases as a function of age of the animal (Table 2). These data thus parallel the age-related differences observed in the recovery of mice from zoxazolamine paralysis.

Table 1 Recovery of C57BL/6J Male Mice of Different Ages from Zoxazolamine Paralysis

All mice were injected intraperitoneally at 1000±0015 h with the drug at a dose of 0.1 mg/g body weight (as 10 mg/ml. in 0.9% NaCl). The paralysed mice were placed on their backs in individual cages, and recovery time was scored as the interval of time between drug injection and the ability to regain the "righting reflex". Young versus old—$P > 0.95$.

Table 2 Zoxazolamine Hydroxylase Activity *in vitro* of Liver Whole Homogenates from C57BL/6J Male Mice of Different Ages

All animals were killed by cervical dislocation at 1000±0010 h. The livers were removed, chilled, weighed, and 10% (w/v) homogenates were prepared in 0.25 M sucrose. Zoxazolamine hydroxylase activity of whole homogenates was estimated by a spectrophotometric method previously described by others[12,13]. Young versus old—$P > 0.95$.

These results suggest that the sustaining level of activity of the mouse microsomal enzyme system decreases with advancing age, and that this decrease may be correlated with a decrease in function for the whole organism. The observed diminution of zoxazolamine hydroxylase activity may be a result of a progressive loss of genetic template accessibility[14,15]. It is also possible that this system is maintained by a certain necessary level of natural substrate, such as one or several steroid hormones. An age-related decrease in substrate pressure may result in "template atrophy" for the whole system—a gradual irreversible loss of response capacity. Finally, integrated function at different levels of biological organization requires coordinated response, which in turn necessitates efficient communication between cells, tissues, organs and systems. Senescent changes resulting from the loss of temporal organization have been discussed before[15].

Mechanism of Cellular Drug Resistance

CELLULAR resistance to drugs or chemicals, which can be "natural"[1-4] or "acquired"[5,6], is important particularly in the treatment of infectious diseases by antibiotics and of tumour cells by cancer chemotherapeutic drugs. I have investigated the mechanism of cellular drug resistance using mammalian cell lines resistant to actinomycin D. In murine leukaemias[7], HeLa cells[8] and bacteria[9] this resistance has been related to membrane permeability barriers which prevent the interaction of actinomycin D with deoxyguanosine residues in DNA, stopping its pharmacological action. Earlier I had found that L5178Y (mouse lymphoma cell line) and L5178Y/D (actinomycin D-resistant subline) glycosidase[10] and glycoprotein : glycosyl transferase[11] activities, which are important in membrane glycoprotein catabolism and anabolism, were altered in the resistant lines. I have now shown that surface membranes are affected, particularly the glycoproteins and glycolipids and their synthesis in the cells resistant to actinomycin D. In this article I shall develop the hypothesis that acquired drug resistance occurs through selection of cells with altered membranes and altered membrane synthetic apparatus, and that such membrane changes decrease drug permeability and thus increase drug resistance.

The cell lines used were DC-3F, derived from normal female Chinese hamster lung tissue, and DC-3F/ADX, a subline of DC-3F resistant to and grown in the presence of 10 μg per ml. of actinomycin D. Details of cell culture, resistance and maintenance were as described before[12]. Initial clones were provided by Dr J. L. Biedler. All enzyme assays were performed on cells which were homogenized for thirty strokes in 5 volumes of 0.1% 'Triton X-100' in 0.1 M Tris-HCl buffer (*p*H 7.6) with a Ten Broeck homogenizer. Glycosidases, acid phosphatase, proteolytic activity, 5′-nucleotidase, UDPase, esterase, succinic dehydrogenase, monoamine oxidase, phosphodiesterase, ribonuclease, deoxyribonuclease and the highly specific glycoprotein : glycosyl transferases, collagen : glucosyl, glycoprotein : galactosyl, collagen : galactosyl, fetuin : fucosyl, PSM : fucosyl, fetuin : N-acetylglucosaminyl, and polypeptidyl : N-acetylgalactosaminyl were analysed for and are described as given in previous publications[10,11,13].

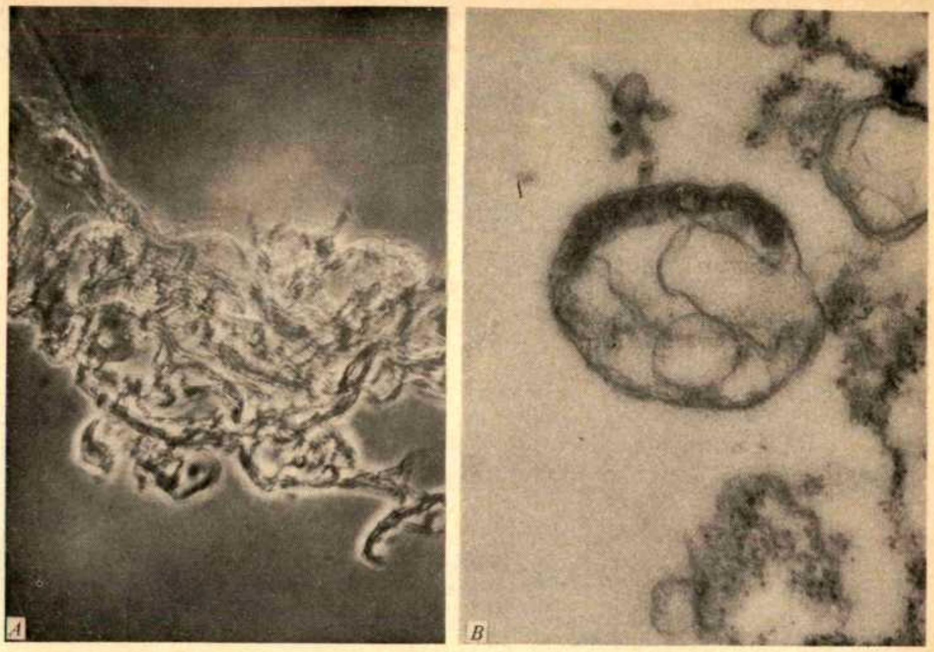

Fig. 1 *A*, Phase micrograph of plasma membrane preparation of DC-3F cells (×384). The cell membranes tend to form aggregates. Little contaminating material is present. *B*, Electron micrograph of plasma membrane preparation of DC-3F cells (×20,000). Dense particles are attached to some of the membranes as reported by Barland and Schroeder[14]. Some bilayer structure is present.

Plasma membranes were prepared by the method of Barland and Schroeder[14]. Fig. 1 indicates electron and phase micrographs of the plasma membrane preparations. The preparations were slightly contaminated with ribosomes and nuclei. Total carbohydrate was determined by the anthrone procedure[15], fucose by the Dische procedure[16] and sialic acid by the Svennerholm procedure[17].

Cell electrophoresis was performed with a thin walled cylindrical cell in a particle micro-electrophoresis apparatus, mark II (Rank Bros., Bottisham, Cambridge) according to the method of Cook and Jacobson[18]. Sodium dodecyl sulphate (SDS) polyacrylamide gel electrophoresis of plasma membrane proteins and glycoproteins was performed without dialysis by the miniprotein method of Laico *et al.*[19]. Gels were stained with Coomassie brilliant blue for protein or a PAS technique for glycoprotein as described[20]. Gels were fractionated by a Savant autogel divider for counting.

To release material from the cell surface, cells were incubated with papain by the method of Walborg *et al.*[21] as described[11]. Analytical procedures for determining composition of the plasma membrane are as given[22].

The DC-3F cells had an electrophoretic mobility in physiological saline at 25° C of -1.65 ± 0.018 and the DC-3F/ADX of -1.75 ± 0.022 μm/s/V/cm, a statistically significant difference ($P < 0.01$), indicating more net negative charge located upon the resistant cell surface. Sizing of the cells on a Coulter counter indicated the cells were of equal volume. The drug resistant cell line is thus characterized by more charged groups

Table 1 DC-3F and DC-3F/ADX Cells and Incorporation of Radioactive Precursors into Plasma Membrane Proteins, Glycoproteins and Glycolipids

Precursor	Treatment	Whole cell, cell line DC-3F	Whole cell, cell line DC-3F/ADX	Plasma membranes, cell line DC-3F	Plasma membranes, cell line DC-3F/ADX
^{14}C-UDP-N-acetylglucosamine	TCA	114 ± 4	322 ± 19	—	—

Cells (10^7) were incubated with 0.5 μCi of ^{3}H-uridine (10 Ci/mmol), ^{3}H-thymidine (10 Ci/mmol), ^{3}H-leucine (10 Ci/mmol.), ^{3}H-fucose (10 Ci/mol), ^{3}H-glucosamine (1 Ci/mmol), ^{14}C-choline (10 Ci/mol), ^{14}C-GDP-fucose (100 Ci/mol), ^{14}C-UDP-glucose (specific activity 240 Ci/mol), ^{14}C-UDP-galactose (specific activity 240 Ci/mol), ^{14}C-GDP-mannose (specific activity 241 Ci/mol), ^{14}C-UDP-N-acetylglucosamine (specific activity 40 Ci/mol), ^{14}C-UDP-xylose (specific activity 100 Ci/mol), ^{14}C-UDP-arabinose (specific activity 100 Ci/mol), or ^{14}C-UDP-N-acetylgalactosamine (specific activity 40 Ci/mol) (purchased from New England Nuclear Corp.) in Eagle's minimal essential medium for 30 min. After incubation the mixture was made 10% in TCA, centrifuged, the pellet washed four times with 10% TCA and once with diethyl ether : ethanol (1 : 2, v/v), dissolved in 1 N NaOH, plated on a glass fibre filter and counted in a liquid scintillation counter[13]. This treatment is referred to as TCA. Alternatively after incubation 1 ml. of H_2O was added to each assay tube, the mixture was boiled for 2 min, then cooled in ice. 0.5 ml. of chloroform : methanol (2 : 1 v/v) was added to the tube and the contents were mixed with a Vortex mixer. After centrifugation at 500*g* for 2 min to break up the emulsion, the upper aqueous layer and the entire white precipitate at the interface were removed by aspiration through a Pasteur pipette and discarded. The resultant chloroform layer was then extracted with 0.5 ml. of water; the aqueous phase was discarded. To measure total lipid or glycolipid synthesis with any of the precursors, an aliquot of the chloroform extract was pipetted directly onto a glass filter, dried and the radioactivity determined in a Beckman liquid scintillation counter[13]. Data are means ±1 s.d. of c.p.m./mg protein. "Whole cell" refers to experiments performed as above. "Plasma membranes" refers to incubation as above for 1 h at 37° C with the indicated precursor followed by preparation of plasma membranes and extraction as given. (—) indicates the experiment was not performed.

Table 2 Chemical Composition of DC-3F and DC-3F/ADX Plasma Membranes and of Macromolecular Species released by Papain Digestion

Chemical composition	Cell line DC-3F	 DC-3F/ADX
	μg/mg protein	
Phospholipid	306.4	312.9
Cholesterol	190.0	186.3
RNA	8.9	9.2
Hexosamine	36.2	109.3
Sialic acid	3.6	14.4
Hexose	89.7	136.4
Papain digest*	μg/10⁹ cells	
Anthrone†	840	1,790
Fucose	200	491
Sialic acid	190	450

* Each sample represents material obtained from 10^9 cells. Papain digestion and assays were carried out as described in the text.

† Reported as μg glucose equivalents/10^9 cells.

—presumably sialic acid[18]—on its surface. To determine whether rates of synthesis of nucleic acids, proteins, glycoproteins, lipids, or glycolipids were different in the drug resistant cells, the experiments given in Table 1 were performed. The data clearly indicate that in the drug resistant cells glycoprotein synthesis was greatly increased over that in the parent cell line, while DNA, RNA and lipid synthesis (choline incorporation) were identical in the two cell lines. There was a slight decrease in protein synthesis (leucine incorporation) in the DC-3F/ADX cell line compared with the normal cell line and glycolipid synthesis was increased slightly but significantly in the DC-3F/ADX line compared with the DC/3F line. The most dramatic finding is that glycoprotein synthesis is greatly enhanced in the drug resistant cell line.

To determine whether the increased synthesis resulted in increased deposition of the glycoproteins and glycolipids in the plasma membranes of the cells, the experiments described in Table 1 were performed. The data show that in the DC-3F/ADX much greater amounts of glycoprotein and glycolipid were found in the plasma membranes even though the amounts of ^{14}C-choline in lipid and leucine in protein were similar in DC-3F and DC-3F/ADX.

Table 2 shows that the plasma membranes of the normal and drug resistant cell lines had similar amounts of cholesterol, phospholipid and RNA, but that the DC-3F/ADX had three times as much hexosamine, four times as much sialic acid, and one and a half times as much hexose as the parent cell line. That the material was near the cell periphery is shown by the data in Table 2, in which papain treated DC-3F/ADX cells released more than twice as much anthrone positive material, fucose and sialic acid as the DC-3F cells released on papain treatment.

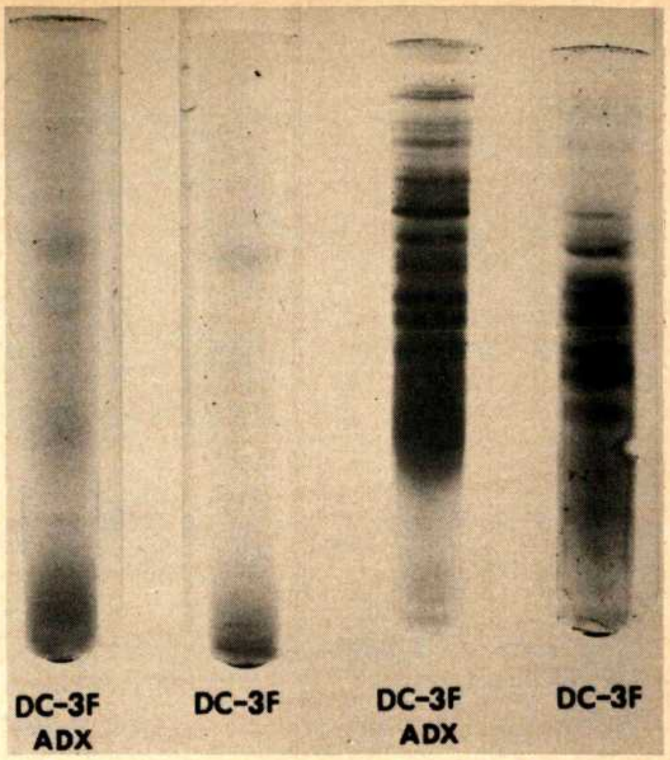

Fig. 2 Polyacrylamide gel electrophoresis of SDS extracts of DC-3F and DC-3F/ADX cell plasma membranes and identification of glycoproteins synthesized by the cells and present in the cell plasma membrane. Cells were labelled with ^{3}H-fucose and ^{14}C-glucosamine as given in Table 1. Cell plasma membranes were prepared and electrophoresis on SDS gels performed. Gels were fractionated and radioactivity was determined. Arrows indicate glycoproteins present in DC-3F/ADX not present in DC-3F. 5% polyacrylamide; *p*H 7.1, 0.1% SDS in samples, gels, and buffers.

Fig. 2 demonstrates that the DC-3F/ADX cell plasma membranes contained more protein and glycoprotein bands on

Table 3 Levels of Enzymes involved in Glycoprotein Synthesis and Degradation in DC-3F and DC-3F/ADX Cells

Enzyme	Endogenous receptors DC-3F/ADX	 DC-3F	Exogenous receptors DC-3F/ADX	 DC-3F
Collagen : glucosyl	2,800 ± 211	900 ± 27	3,100 ± 409	900 ± 49
Glycoprotein : galactosyl	5,700 ± 206	2,200 ± 107	4,100 ± 273	800 ± 36
Collagen : galactosyl	4,100 ± 310	2,000 ± 119	2,400 ± 166	1,000 ± 47
Fetuin : fucosyl	1,000 ± 42	250 ± 4	2,200 ± 217	900 ± 58
PSM : fucosyl	2,100 ± 49	1,200 ± 92	1,900 ± 88	800 ± 69
Fetuin : N-acetylglucosaminyl	3,500 ± 220	1,700 ± 43	3,700 ± 16	1,400 ± 101
Polypeptidyl : N-acetylgalactosaminyl	1,100 ± 106	480 ± 27	1,800 ± 14	1,000 ± 43
α-fucosidase	141 ± 9	300 ± 11		
β-fucosidase	1 ± 0.2	9 ± 1		
β-xylosidase	23 ± 2	25 ± 3		
α-mannosidase	19 ± 2	30 ± 2		
α-glucosidase	5 ± 1	14 ± 1		
β-glucosidase	0	0		
α-galactosidase	24 ± 2	117 ± 6		
β-galactosidase	88 ± 6	201 ± 3		
β-N-acetylgalactosaminidase	4 ± 0.3	204 ± 6		
β-N-acetylglucosaminidase	75 ± 3	1,796 ± 36		
Acid phosphatase	1,169 ± 40	1,270 ± 36		

Data for glycosidases and acid phosphatase are given as nmol/h/mg protein. Data for glycoprotein : glycosyl transferases are given as c.p.m./mg protein. Cells were extracted and assays performed as given in the text. Means ± 1 s.d. Endogenous and exogenous refer only to the glycoprotein : glycosyl transferase data.

SDS gel electrophoresis. The data in Fig. 2 show that labelling of the glycoproteins with fucose and glucosamine indicates several new glycoproteins are present in the DC-3F/ADX cell plasma membrane not present in the DC-3F cell plasma membrane.

Two means of increasing glycoproteins on the cell surface would be either to decrease glycosidase activity (enzymes which degrade glycoproteins) or to increase activity of glycoprotein : glycosyl transferases (enzymes which synthesize glycoproteins). The data in Table 3 clearly indicate that in the DC-3F/ADX cell line glycosidase activity (but not acid phosphatase) was lower than in the DC-3F cell line. Conversely, as Table 3 shows, glycoprotein : glycosyl transferase activity using either endogenous or exogenous acceptors was greatly increased in the DC-3F/ADX compared with the DC-3F cell line. Both changes would lead to enhanced content of glycoprotein in the drug resistant cells. All other enzyme levels measured (see above) showed similar activity in DC-3F/ADX and DC-3F.

The results of this communication implicate plasma membrane changes in glycoprotein and glycolipid content as determining factors in drug resistance. Whether these changes in glycoprotein content lead to permeability barriers to drug (in this instance actinomycin D) and are not simply a result of selection of drug resistant cell mutants is not known. But a mechanism—increased glycoprotein: glycosyl transferase activity and decreased glycosidase activity—has been advanced for the changes in plasma membrane glycoprotein content, although it is not yet clear whether this is general. It is, however, a working hypothesis at the biochemical level for cellular drug resistance.

This work was supported in part by grants from the US National Institutes of Health and the American Cancer Society. I am a Research Career Development awardee of the National Institute of General Medical Sciences. I thank Dr June L. Biedler for the initial clones of cells and for advice, Dr David Kessel for discussions, Mrs Gerilyn Z. Pike, Miss Melinda B. Shea and Mr Kenneth R. Case for technical assistance, Mr William Carlson and Miss Maryanne Puerner for the whole cell electrophoresis measurements, and Dr Charles Yuile for the electron microscopy.

Anal Gland Secretion of the Red Fox

LITTLE is known of the chemistry of odour in higher animals[1-4] in relation to the importance which behavioural studies have ascribed to it[5-7]. Those chemical studies which have been undertaken have often lacked a concern for the behavioural and ecological implications of odour, although exceptions to this rule are becoming more numerous[2,8,9]. Here we describe preliminary chemical studies on the nature of the anal gland secretion of the red fox (*Vulpes vulpes fulva*, L.). An account of related behavioural studies will appear shortly[10]. Further chemical studies on the nature, variability and significance of the volatile components of the anal gland secretion of the red fox and of other Canidae are in progress. Microbiological studies are also planned[11].

Anal gland secretion obtained from a 1-yr-old female red fox was found to contain at least twelve volatile components including a base, trimethylamine, and a series of saturated carboxylic acids (C_2 to C_6). Among the acids, acetic acid, propionic acid, *iso*-butyric acid and *n*-butyric acid were definitely identified and evidence suggests that the remaining components included 3-methylbutanoic acid with some 2-methylbutanoic acid, pentanoic acid and 4-methylpentanoic acid.

Anal gland secretion, although sometimes released by the alarmed animal, was routinely obtained by massage of the anal glands. The slightly yellow, odorous, aqueous liquid was collected in capillaries and centrifuged to remove suspended solid. About 0.5 ml. secretion could be obtained at one time. Slight variations in secretion properties were observed from sample to sample (odour, colour, *p*H 8.2 to 8.5). Samples contained much soluble protein.

Table 1 · Gas Chromatography of Unmethylated Anal Gland Secretion *

Time (min)	Column temperature	Component	Relative molar concentration in typical sample
0.7	185	A	Minor components eluted with water
1.8	185	B	
2.7	185	C	
7.5	185	D	100
10.9	185	E	Very variable
16.9	185	F	23
28.8	200	G	9.1
32.3	200	H	13
49.4	210	I	7.3
56.4	210	J	0.95
87.9	210	K	11.4

* 'Porapak Q' column.

The centrifuged secretion was examined, without further processing, by gas chromatography using an F and M 810 chromatograph (FID) with a 6 foot × 0.25 inch silanized glass column of 'Porapak Q' (80–100 mesh) and operated at 185° C rising to 210° C with helium carrier gas. Eleven volatile components were clearly resolved although the first three, minor components with retention times similar to that of water, were not studied (Table 1).

Variations of three types were noted between secretions taken from the same animal on different occasions. First, an order of magnitude variation in the overall concentration of all volatiles was observed. Some secretions were volatile rich, others volatile poor. Secondly, although compounds corresponding to peaks D, F, G, H, I, J, K were generally present in approximately the same relative proportions, G/H and D/F variations were most pronounced. One component, E, was often a relatively minor component of the mixture, but at least once this component was observed to be present in greater amounts and on this occasion the solution was more alkaline than usual (*p*H 8.5).

Mass spectra of secretion components were obtained by combined gas chromatography–mass spectrometry. Using an LKB 9000 mass spectrometer (70 eV) with a 'Porapak Q' column and helium carrier, spectra corresponding to peaks E (*m/e*: 59, *58*, 42, 30)*, D (*m/e*: 60, *45*, 43) and F (*m/e*: *74*, 73, 57, 45) were identified as those of trimethylamine, acetic acid and propionic acid respectively following detailed comparison with spectra of authentic materials run under identical conditions and by reference to the literature[12]. The spectra of G (*m/e*: 88, 73, *43*, metastable 60.5) and H (*m/e*: 88, 73, *60*) suggested *iso*-butyric and *n*-butyric acids respectively. The spectra of I, J, K suggested higher saturated carboxylic acids. To facilitate identification of these higher acids, the secretion was acidified, extracted with ether and the extract methylated with diazomethane. The resulting solution was again examined by gas–liquid chromatography–mass spectrometry using an OV-17 column (3%) for the higher acid esters and a 'Porapak Q' column for the lower acid esters. On 'Porapak Q' at 200° C, following the solvent peak, peaks for methyl *iso*-butyrate, G (*m/e*: 102, 87, 71, 59, *43*), methyl *n*-butyrate, H (*m/e*: 102 (very weak), 87, 74, 71, 59, *43*), a pentanoic acid methyl ester, I (*m/e*: 116 (very weak), 101, 88, 85, 74, 59, *57*, 41) and a hexanoic acid methyl ester, K (*m/e*: 115, 99, 88, 87, *74*, 59, 57, 55, 43) were identified by comparison with spectra of authentic materials. Other components were either present in too small quantity to give useful spectra, or were eluted with the solvent. The presence of higher acid esters was examined using an OV-17 column at 160° C. Only one peak was observed beyond the solvent peak and this gave a mass spectrum identical with that of the final peak on 'Porapak Q'. No peaks due to higher fatty acid esters, at least as far as the C_{10} acid, were observed. In all cases, gas–liquid chromatographic retention time data were recorded with precision and compared with those of authentic samples to aid the identification of components.

A series of saturated carboxylic acids (C_2 to C_6) and the base, trimethylamine, were thus identified in the anal gland secretion. Mass spectrometry and gas–liquid chromatography retention time data clearly identified trimethylamine, acetic acid, propionic acid, *iso*-butyric acid and *n*-butyric acid as components E, D, F, G and H of the secretion. The isomers of the C_5 and C_6 acids present were not so clearly defined. The mass spectrum of peak I in the unmethylated sample, when compared with published data[12], together with a consideration of gas–liquid chromatography retention time data strongly suggested that peak I was of C_5 saturated carboxylic acid, probably a mixture of 3-methylbutanoic acid (base peak 60) with some 2-methylbutanoic acid (base peak 74). An examination of the corresponding mass spectrum in the methylated sample supported this. The mass spectrum closely resembled that of 3-methylbutanoic acid methyl ester with the exception of certain anomalous peaks. Thus the unexpectedly intense peak at *m/e* 88 could arise by McLafferty rearrangement from some 2-methylbutanoic acid methyl ester present with the 3-methylbutanoic acid methyl ester. Also the gas–liquid chromatography peak in question, although apparently "pure", was slightly shifted from the position of 3-methylbutanoic acid and this could be accounted for on the basis of the presence of an admixture of a second unresolved component of similar retention time to that of the 3-methylbutanoic acid.

The compound present in peak J was not easily identified, for no good mass spectra were obtained of this very minor component. The gas–liquid chromatography retention time and the dominance of peaks at *m/e* 60 and 73 in the unmethylated material's mass spectrum suggested the possibility of this being *n*-pentanoic acid.

Peak K was produced by a C_6 saturated carboxylic acid. Gas–liquid chromatography retention time data excluded the possibility of this being *n*-hexanoic acid. The mass spectrum of the methylated sample exhibited some differences from that of the methyl ester of 2-methylpentanoic acid and considerable differences from that of the methyl ester of 3-methylpentanoic acid. At the time of the study no authentic sample of the methyl ester of 4-methylpentanoic acid was available, but features of the mass spectra of both the methylated and unmethylated samples suggest this assignment.

The anal gland secretions were further examined by gas–liquid chromatography for the presence of less volatile odorous components using a column of 10% 'Carbowax 20M' on 'Gas Chrome Q' at 200° C. In these conditions, the retention times of 3-methylbutanoic and 3-methylpentanoic acids were 1.2 and 1.8 min respectively. On examining the unmethylated secretion, only one peak could be observed at retention time greater than 1.8 min. This was at 5.14 min (peak L). The nature of this component is now under examination. Neither indole (r_t 12.9 min) nor 3-methylindole (r_t 14.8 min) was present.

In a typical secretion sample, the relative molar concentrations of volatiles was estimated as in Table 1 by the use of gas–liquid chromatography. In this case the absolute concentration of acetic acid was 0.28 M. The trimethylamine peak was not quantified but it was clearly insufficient alone to account for the alkaline *p*H of the solution.

Using the method of Beutler *et al.*[13], the presence of thiol was sought in a secretion sample from which all solid and soluble protein had been removed. Thiol was detected at a level of 3.25×10^{-5} M. It is possible that these small quantities of thiol are not present in volatile form, but as, for example, glutathione.

BOOK REVIEWS

Industrial Crystallization

Industrial Crystallization from Solutions. By Jaroslav Nyvlt. Translated by Paul Feltham. Pp. 189. (Butterworth: London, July 1971.) £5.50.

CRYSTALLIZATION, the practice of which dates back to antiquity, is one of the major processing techniques of the chemical industry. Yet it is only in recent years that serious attention has been paid to this old established and long neglected unit operation of chemical engineering.

Without doubt, crystallization is an exceedingly complex operation. It is a simultaneous heat and mass transfer process with a strong dependence on fluid and particle mechanics. It takes place in a multi-phase, multi-component system. It is concerned with particulate solids whose size and size distribution, both incapable of unique definition, vary with time. Nucleation and growth kinetics, the governing processes in this operation, can often be profoundly influenced by mere traces of impurity in the system.

It is, perhaps, no wonder that crystallization has been called an art rather than a science. Nevertheless, industrial crystallizers have to be designed and operated, in spite of the fact that the foundations are somewhat insecure. Any publication, therefore, which attempts to increase available knowledge of this complicated subject is more than welcome.

The author is head of the industrial crystallization section at the Czechoslovak Research Institute for Inorganic Chemistry at Usti Nad Labem. The book, which is an extensively revised version of the original 1967 Slovak language edition, is in two parts. The first deals with theoretical analyses of phase equilibria, material and thermal balances, nucleation and crystallization kinetics and growth behaviour in multiparticle systems. Experimental techniques for measuring kinetic data and equilibria are also described. The second part covers the industrial practice of crystallization. Several basic types of crystallizer are described, and pathways leading to the design of these units are explored. A number of useful worked examples are given.

Most of the mathematical models utilized in this book were devised by the author, and it is very interesting to compare and contrast them with those that have been derived in the past decade or so by research workers in the United States and the United Kingdom. In any case, a large proportion of the author's publications have appeared in Czechoslovakian journals only, so it is most instructive to have this summary of them in the English language. Furthermore, another valuable feature of this book is the fact that it introduces the reader to a considerable amount of virtually inaccessible information published in a wide variety of East European journals.

J. W. MULLIN

Statistical Mechanics

Statistical Mechanics at the Turn of the Decade. Edited by E. G. D. Cohen. Pp. viii+235. (Marcel Dekker: New York, January 1971.) $12.50; £5.95.

THIS book is a record of the symposium held at North Western University, Evanston, Illinois, in October 1969 to celebrate the seventieth birthday of Professor G. E. Uhlenbeck. It consists of a verbatim record of the eight lectures given at the symposium, and forms a fitting tribute. The style of the lectures is lucid and contrasts favourably with that of the usual formal layout of research publications: they are decidedly readable. I particularly like the way some of the authors review the major work of past papers in their topics with a frank and searching criticism not usually found, and anticipate the direction of further developments in their fields. Each lecture is well referenced, and for the most part they all contain brief (sometimes too brief for the uninitiated) introductions. If the book has to be faulted, it could be said that it is too broadly based, in that I feel that most people working in statistical mechanics and allied fields will find something of interest, but they may not be conversant with the work outlined in many of the sections.

In the section on statistical mechanics and ergodic theory, A. S. Wightman contributes a cohesive and well documented discussion of developments in classical statistical mechanics, including good introductory sections, and remarks on the seeming paradox of microscopic reversibility giving macroscopic irreversibility. He goes on to consider certain Hamiltonian flows and K and S systems in some detail.

The generalization of the Boltzmann equation to higher densities is covered by E. G. D. Cohen in a very well written section outlining the investigations into the density distribution functions for moderately dense gases, incorporating the concepts of multiple particle collisions. The author concludes with astute remarks on the major difficulties of the problems.

D. Ruelle contributes a short section on the C* algebra approach to statistical mechanics. Time evolution of quantum systems and, eventually, decomposition equilibrium states are dealt with. Possibly this discussion would be better fitted to a book on quantum mechanics.

The lectures on the Curie point, given by C. Domb, occupies the longest and most readable section of the book, with a comprehensive literature survey. The introductory parts could well be used for undergraduate reading. The principal consideration here is with the position of the attempted reconciliation of the approaches of Onsager and Van der Waals to this transition.

F. J. Dyson provides a good sequel to the talk of Professor Domb with a section on phase transitions in ferromagnets. He considers some interesting and inter-related problems concerning phase transitions for the Ising model of a ferromagnet, and how these relate to the Heisenberg model.

The varying fortunes of the Weiss ferromagnetic theory and the Van der Waals theory of gas-liquid systems, and their status in the light of modern developments are the topics of A. J. F. Siegert's contribution.

P. C. Martin reviews superfluids and superconductors, first describing superfluidity and its thermodynamics and hydrodynamics. He concludes with a discussion of non-equilibrium problems of vortex motion, supercurrent decay and fluctuations near the transition temperature.

Finally, P. C. Hohenberg deals with dynamic phenomena near a critical point. First there is an exposition on the static properties near a critical point as given by Professor Domb; then an interesting, but non-rigorous, approach to dynamic critical phenomena which gives good agreement with experimental results.

J. E. JONES

Fluorine Journal

Journal of Fluorine Chemistry. Edited by H. J. Emeléus and J. C. Tatlow. Pp. 128. (Elsevier: Lausanne, July 1971.) n.p.

THE quality of the papers in the first issue of the new quarterly, *Journal of Fluorine Chemistry* is much the same as that found in most learned society journals.

Each paper was carefully scrutinized by one senior referee and by one of the two distinguished editors-in-chief. The editors have informed me that, if they themselves have any doubts about papers submitted for future issues of the journal, the manuscripts will also be examined by a second referee. Refereeing procedures, therefore, should be as tough as those employed by the more reputable journals.

Provided the determination of the editors to stop this journal becoming a depository for papers rejected elsewhere is maintained, and, if the editorial board continues to exercise a critical vigilance, there is every reason to hope that the standard of the first issue will be upheld.

I note with concern, however, that this is yet another specialist journal which now has to be perused. The proliferation of specialist periodicals during the last few years is a trend to be abhorred, partly because of their tendency to lower standards and partly because their very nature encourages narrow specialization which has a detrimental effect on the progression of science. Furthermore, in the present economic situation, libraries are being forced to become more and more selective in what they purchase and inevitably, if this trend continues, some journals must fail. A relatively expensive, specialist quarterly, such as *Journal of Fluorine Chemistry*, must surely be one of the most vulnerable.

J. H. HOLLOWAY

School Physics

PSSC Physics. By Uri Haber-Schaim, Judson B. Cross, John H. Dodge and James A. Walter. Third edition. Pp. 674. (Heath: Lexington, Massachusetts, and Farnborough, Hampshire, March 1971.) £4.

THIS is the third edition of a really most attractive elementary introduction to physics, a text which by now is firmly established in the United States. It is essentially aimed at a school leaving standard more or less corresponding to our A-level. Its 674 pages cover quite an extensive range, including optics, gravitation, energy, electrostatics, electromagnetics, elements of atomic structure, quanta and matter waves. The illustrations throughout the book are magnificent. The text is mainly descriptive, depending heavily on well drawn, and often amusing, illustrations, backed with a solid sprinkling of admirable photographs, some in colour and all very much to the point. The very backbone of the whole text is the many fine illustrations, for there is hardly a page but that it has one or more of these, all well drawn, cleverly designed and very informative.

There are perhaps one or two weaknesses in the text. The optics section is largely purely descriptive, at times a little superficial. Although, as elsewhere, the 160 pages devoted to optics have numerous delightful illustrations, yet there is, I think, a decided lack of derivation of elementary formulae, indeed not enough for O-level, much less A-level physics. However, when the reader moves straight on to the next sections (motion in a straight line and vectors) this defect is corrected. Especially clear and attractive are the sections on Newton's laws of motion and on gravitation, with just the right loading of mathematics for the A-level candidate. Since this quite essential amount of mathematics is correctly included here, all the more does one feel the weakness due to the paucity of simple mathematical treatments in the earlier fairly large section on optics. Much clever use is made of stroboscopic and interrupted photographs of moving objects to illustrate dynamical principles.

There follows a short section on the kinetic theory of gases which is excellent. There is a curiosity in the succeeding electrical section. It is perhaps a criticism that the description of the cathode ray tube and the use of the oscilloscope come even before the derivation of Coulomb's law in electrostatics. This seems to be giving in to modern popular expectations at the expense of a logical teaching sequence. A similar curiosity appears as early as page 5 of the text. Surely this is much too early to illustrate a large bevatron and even to write about "a common place Geiger counter". Such excitements should be left for later. This reminds me of a school I visited in the United States where boys were "familiar" with the use of a Geiger counter before they had been taught Ohm's law. Surely there is a very real educational danger in by-passing basic fundamentals early for the sake of modern (admittedly exciting) applications.

The sections of the text dealing with the magnetic field and electromagnetics are practical, well illustrated and backed up by just the right amount of mathematics. The chapters on the Rutherford atom, photons, atomic spectra and the wave theory of matter are all compact, adequate and treated with sympathetic understanding for the difficulties the schoolboy will encounter.

Each chapter has a set of problems and a book list for further reading. My only real criticism is that there is no section on acoustics, which lends itself admirably to the illustrative type of treatment used throughout this book. Production is first rate and the price reasonable, although high by school standards in this country. Yet this is a text of which there should certainly be more than one copy in every school library in this country. I welcome this new edition. S. TOLANSKY

Ionic Interactions

Ionic Interactions: From Dilute Solutions to Fused Salts. Vol. 1: Equilibrium and Mass Transport. Edited by S. Petrucci. (Physical Chemistry: a Series of Monographs, Vol. 22.) Pp. xiii+407. (Academic: New York and London, February 1971.) $19.50; £9.10.

THE word "Interactions" in the title must be read in nearly all of its connotations in order to connect the miniature monographs in this volume. It means the long range mutual electrostatic interactions of many ions in dilute solutions; it means the short range interactions which, depending on the forces and partners involved, lead to ionic association, solvation or complexation; in the second volume, interaction of ions with radiation will be included. Two types of interaction are omitted—chemical interactions of ions with other ions or molecules, and electrochemical interactions at the electrode–electrolyte (fused or solution) interface.

The first chapter, by H. Falkenhagen and W. Ebeling, presents a theoretical treatment of the equilibrium properties of dilute solutions of strong electrolytes. The classical limiting laws of Debye and Hückel for osmotic and activity coefficients are derived, first for point charges, and then for charged rigid spheres in a continuum. After a brief discussion of the limitations imposed by the linearized Poisson–Boltzmann equation, general molecular distribution functions are derived by the method of Bogoliubov; these lead to the thermodynamic properties as functions of concentration. Finally, ionic association as a consequence of electrostatic attraction is considered; the association constant is evaluated by requiring identity of corresponding coefficients in equations derived respectively for the physical model and the chemical model. The second chapter, by H. Falkenhagen, W. Ebeling and W. D. Kraft, summarizes the theory of electrolytic conductance as developed by the electrolyte school at Rostock University. First, the equation for the limiting tangent is derived, following the classical Debye–Hückel–Onsager approach. The authors then proceed to review their attack on the problem of irreversible processes in electrolytic solutions (conductance, in particular) which begins with a derivation of the fundamental equation of continuity from the exact Liouville equation of statistical mechanics. Solution of the former for the pair correlation function leads to the relaxation force. The electrophoretic effect is derived from the generalized diffusion equation of Falkenhagen and Ebeling. Combination of these two long range interionic effects then gives the conductance function for unassociated electrolytes. Finally, the consequences of ionic association due to electrostatic attraction are treated by a method which parallels that used in the first chapter for reversible processes.

In the third chapter S. Petrucci reviews the various statistical and thermodynamic approaches to the still incompletely resolved question of ion association. These include Bjerrum (1926), Fuoss (1934), Fuoss (1958), Denison-Ramsey (1955), Gilkerson (1956), and Bruckenstein-Pettit (1966). Complexes of ions and neutral ligands are next discussed, from the point of view of crystal field theory. The chapter concludes with a description of the methods of calculating association constants from experimental data on galvanic cells, conductance, and absorption spectra.

In the fourth chapter J. Braunstein describes the transition from very dilute aqueous solutions (the domain of the first three chapters) to fused salts with concentrated solutions, hydrate melts, and melts with less than enough water for complete hydration as intermediate stages. Theory of the thermodynamic properties of these systems requires a change of model as one goes from dilute solution to fused salt; a cell model begins to replace the continuum in the moderately concentrated range, and finally fused salts are best represented by the randomized crystal lattice. Transport properties of fused salts are the subject of the fifth chapter, by C. T. Moynihan. Experimental results on conductance, diffusion, viscosity (shear and bulk), and transport numbers are first reviewed in sufficient breadth to set the stage for a critical presentation of the many theories which have been advanced to describe irreversible processes in fused salts. These include the Stokes–Einstein equation, the Nernst–Einstein equation, transition state theory, significant structure theory, the hole theory, statistical mechanical theories, the free-volume theory, and the Adams–Gibbs theory. The chapter concludes with sections on relaxation phenomena in fused salts and transport processes in fused salt mixtures.

Raymond M. Fuoss

Antimicrobial Action

Biochemistry of Antimicrobial Action. By J. T. Franklin and G. A. Snow. Pp. ix+163. (Chapman and Hall: London, July 1971.) £2.25.

The field of antimicrobial mechanisms of action has developed rapidly in the past twenty years. This book describes chiefly the principal known features of the mechanism of action of antimicrobial drugs. It is well up to date but, unfortunately, does not deal, in most cases, with details of the experimental approaches leading to the main discoveries. In spite of this, the book should be very useful for beginners because it provides important basic information about the biochemical action of antimicrobial drugs.

The book comprises seven chapters dealing sequentially with (1) a general outline of the development of the field and different approaches to investigate the biochemical action of antimicrobial agents; (2) drugs affecting synthesis of the bacterial cell wall peptidoglycan; (3) antiseptics and antibiotics interacting with the membrane; (4) inhibitors of nucleic acid synthesis; 5) inhibitors of protein synthesis; (6) antifolic agents and inhibitors of respiration, inhibitors of metabolite uptake and miscellaneous inhibitors; and (7) resistance to antimicrobial agents.

In dealing with the different drugs there is, throughout the book, an emphasis on the compounds important for clinical use. In this respect, however, there are a number of important omissions, including colistin and gramicidin A (in the group of antibiotics acting on the membrane), streptovaricin and streptolydigin (inhibitors of bacterial RNA polymerase), daunomycin and adriamycin (intercalators between the base pairs of DNA), doxycicline, spiramycin and oleandomycin (inhibitors of bacterial protein synthesis) and emetine (inhibitor of eukaryotic protein synthesis).

Editing and presentation of the book are good. The list of references is reduced but moderately well selected. The book is very pleasant to read and data are presented carefully and clearly. It can be easily understood even by readers without a solid background in the subject. I particularly enjoyed the seventh chapter which deals with the problem of resistance to antimicrobial drugs. I strongly recommend this book as an introduction to the field for students of biology and medicine.

D. Vazquez

Kidney Hormones

Kidney Hormones. Edited by J. W. Fisher. Pp. xviii+665. (Academic: London and New York, March 1971.) £8.

Dr J. W. Fisher has edited a first-rate book on kidney hormones. I am puzzled, however, as to why these hormones, so disparate in function, are included in one volume. Perhaps because the enzyme renin is closely associated with erythropoietin in the juxtaglomerular cells, this is thought to be reason enough. And then the kidney is involved in the anaemia which accompanies chronic nephritis, and erythrocytosis is associated with some renal tumours. Nevertheless, like so many such conglomerates there are chapters whose relevance even to kidney hormones is questionable. Blood flow, oxygen utilization and distribution of blood flow are interesting and well exposed but it is not made explicit why they belong in a book on renal hormones.

The authors of the twenty-five sections are among the most competent in their fields, ensuring the quality of their judgment and writing. Two hundred and thirty-eight pages of the book are given to erythropoietin, 179 to angiotensin and 118 to prostaglandins, vasoactive renal lipids and kinin-forming enzymes. An interesting cross-over is provided by Gallagher's chapter on polycythaemia and erythropoietin production in hypertensive patients. Emphasis, however, is largely on the chemical and pharmacological aspects of the hormones, indicating that the book is written for basic scientists by excellent scientists: clinicians beware!

At a cost of £8 and the large amount of time required to read the book one wonders how many investigators will buy it or peruse it. Those of us who live by research in these fields are glad to have the review, even though most of the material is long familiar. The literature on erythropoietin is far less well known to most of us than is that on angiotensin and, therefore, the more welcome.

The editor could have profitably used his blue pencil to the discomfort of his authors in some of the chapters. For example, one wonders about the nearly two full pages in "Studies on the Renal Erythropoietic Factor (REF)" listing in detail the numbers of rats, rabbits, sheep, dogs, pigs, persons, carp, frogs and ducks ("five ducks, one white Peking duck") that were studied but neglecting to tell the reader the results!

It is not the prerogative of a reviewer to expound his own views on needs of investigators: nevertheless, I shall do so. Books being as expensive as they are and the volume of publication so great, the time is overdue for a thoughtful discussion of what constitutes an effective literature review. The range of opinion is still very wide, largely, I think, because it has not been adequately debated. It varies from authors who believe the editor has no more rights than to see to it his manuscript is published, to editors who believe each article must receive the most scrupulous revisions of fact, rhetoric and evaluation. Often to the surprise of both, the reader feels he has a stake in the discussion.

There is a place for short, readable overviews and for comprehensive ones as in *Physiological Review*. There is also room for that rare volume which digests and evaluates the vast literature of such a subject as angiotensin and presents it as a critical, structured review. But I am dubious of reviews which fall between. They are too complicated for the student and clinician, too elementary for the expert and too expensive for those who merely want to give prestige to their bookshelves.

I do not mean that this all applies to Dr Fisher's book but some parts of it might. For what it is, however, I liked the book.

IRVINE H. PAGE

Aldosterone

Aldosterone. By Edith Gláz and Paul Vecsei. (International Series of Monographs in Pure and Applied Biology, Vol. 6.) Pp. 626. (Pergamon: Oxford and New York, June 1971.) £10.00; $27.

THIS review by Gláz and Vecsei has been divided into two sections, bringing together the scientific and clinical aspects of aldosterone research. Vecsei begins his section with a chapter describing the significant publications which led to the suggestion of a salt retaining hormone and eventually to the isolation of aldosterone. For the historically minded this makes interesting reading. The second chapter is concerned with a detailed description of the various indirect and direct methods in the assay of aldosterone. A critical analysis is given in the third chapter of aldosterone metabolism, from its biosynthesis to its circulation in different body compartments and its removal from the body. A chapter is then devoted to the mode of action of aldosterone in various body tissues while the final chapter of this section is used to describe the mechanisms regulating the release of aldosterone.

The section written by Gláz begins by describing the disease of aldosteronism. A wealth of information is provided on the syndromes observed which is followed by an assessment of the diagnostic tests used in studying aldosteronism. Finally, several pages are devoted to the therapeutic measures used in alleviating aldosteronism. The seventh chapter contains sections describing the various diseases where the condition of secondary aldosteronism arises, for example, Bartter's syndrome; nephrotic syndrome; and also sections dealing with the rationale behind these diseases, for example, experimental renal hypertension; experimental neurogenic hypertension. Other forms of aldosteronism and hypoaldosteronism are then discussed in two short chapters. The final chapter concerns the drugs used to treat aldosteronism and their effectiveness, either singly or together, are described.

Although the book is generally well written, there are frequent errors of language. Often the definite article is missing, and phrases such as: "As for a long time . . ." page 134), "It is to be assumed that, thus, also . . ." (page 268) and even an incomplete sentence (page 242) tend to distract the reader. Several of the figures (for example Figs. 22, 28, 30 and 31) need fuller footnotes for them to be understood.

Far more serious is the criticism that in places the text is already out of date and in need of revision. For example, the concept of "adrenoglomerulotrophin" is no longer generally accepted (fifth chapter). Similarly, Gláz fails to state that in 1968 Kinson and Singer (*Endocrinology*, **83**, 1108; 1968) were able to demonstrate angiotensin stimulation of aldosterone secretion in the rat, but only in the sodium deficient state. Again, Vecsei's emphasis on paper chromatographic systems in aldosterone assay is too strong. Today many laboratories are using thin-layer chromatography and gas chromatography in their assay systems, therefore more information on these techniques would have been useful. Indeed, at present methods of protein binding and radio-immunoassay are becoming increasingly important in this field and the application of these procedures could have been discussed.

In spite of these criticisms I can only agree with the aims of the authors as expressed in the preface, that the review is "comprehensive and detailed". They have certainly maintained a "balanced standpoint" on many of the unresolved problems in aldosterone research. This volume is extremely well based and should prove very useful to both newcomers and those deeply involved in this area of interest.

EDWARD J. JOHNS

One Man's Nerves

The Autonomic Nervous System: Morphological, Comparative, Clinical and Surgical Aspects. By Joseph Pick. Pp. xv+483. (Lippincott: Philadelphia; distributed in Great Britain by Blackwell Scientific: Oxford, 1970.)

THIS posthumous work covers the personal research and reading of one man. The book is divided into four sections. The first, on fundamentals of the autonomic nervous system, is the largest part and covers the principles of the system, its development, central connexions and the histology of the autonomic neurones. The whole presentation is largely morphological but the author points out that the increasing complexity of the autonomic nervous system parallels the increasing environmental stresses imposed by the evolution from sea to land. One of the most valuable and interesting chapters is that on the history of the discovery of the autonomic nervous system, based acknowledgedly on the work by Sheehan.

In the second section the author covers the autonomic nervous system in animals ranging through the animal kingdom from *Amphioxus* to the monkey. Throughout these detailed chapters the aim is to show the relationship between the autonomic nervous system of these forms and the more complicated nervous system of man.

The remainder of the book, the third and fourth parts, is devoted to man, the third part being a morphology of the autonomic nervous system in man. This is profusely illustrated with a dissection of major nerve systems using the Zeiss operative microscope, all the fine dissections being checked histologically. Most of the regional autonomic dissections have been done on one cadaver but the microscopic pictures are beautifully reproduced. There is a particularly interesting account of the electron microscopy of the peripheral autonomic system and especially interesting is the electron microscopy of man's autonomic nervous system from foetal life through adolescence, maturity and senescence.

Mary Lorenc, the illustrator, has produced splendid line drawings, some of great simplicity yet serving to clarify the theory most admirably. The black-and-white illustrations are superb and the illustrations of the micro-dissection of plexuses in relation to levels is strikingly brought out in black-and-white with red for the vessels. In places, however, a striving for realism in some of the half-tone plates has obscured the aim of anatomical illustration to clarify and depict a relationship. There is an unusual but extremely effective series of illustrations, combining diagrams against photographic insets of the nerve trunks dissected. All in all, the work owes almost as much to the artist as to the author and of the 300 illustrations very few could be faulted.

The clinical section is exceptionally comprehensive and valuable and the detailed anatomy of many procedures is described and illustrated. Though there is a large section on denervation of the head and extremities by sympathetic ganglionectomy there is no mention of intracranial procedures such as nervus intermedius section or resection of the petrosal nerve, for example. The place of the author in the surgical world is shown by the distinguished surgeons who gave advice and the section on clinical surgery—White, Smithwick and LeRiche to mention a few.

The whole work is a superb reference book which is a "must" for the libraries and which many who work in this field will use as an essential work of reference for many years. It is to be hoped that in spite of the author's death further and up-dated editions will appear.

CORRESPONDENCE

Rapid Publication

SIR,—Your editorial, "Publish and Be Damned a Second Time," is of especial interest because of the experience we had in the US space programme. The answer you arrived at on the question of newspaper reports *vis-à-vis* scientific journals was "publish quickly". This may be the only course for the journals.

In December 1962 the results of the Mariner spacecraft which had journeyed to Venus were ready for dissemination but the scientists involved made a strong case against a press conference until articles could be published in scientific journals. This meant delays of weeks or months and a rather haphazard way to release results from a number of related experiments.

An internal struggle in NASA with the public affairs people arguing for timely release of data (gathered at the taxpayers' expense) versus scientists who insisted on reporting first—and surely not *via* the news media—to the scientific community ensued.

A compromise was worked out using *Science* magazine as a base: press conferences such as the Mariner would be held on the publication day of the magazine. Letters would be submitted, stating the urgency of the matter, to *Science* on a Monday, prearranged immediate attention would be given the letter, publication of preliminary results accepted (or rejected) for that very week and a press conference could be arranged Thursday or Friday. The experimenter would state to the news media that the preliminary results to be presented had been submitted for publication. Acceptance for publication in these cases meant immediate publication, not acceptance today and actual publication months later. Additional later publication of refined results appeared often in other journals, including *Nature*. The experimenter afforded himself protection under this procedure with two *caveats*: publication and the word "preliminary".

As a result, the practice has become increasingly more liberal and, although there have been a few faint cries of "instant science", now the real time reporting of (preliminary) scientific results from space probes has become a practice. Viewers will see in the current Mariner 9 Mars probe real time interpretation of Mars television pictures and press conferences throughout the encounter phase without regard to publication. Publication will come later when careful analysis with all the data is available.

Yours faithfully,

JULIAN SCHEER

Announcements

University News

Dr D. L. Lee, Houghton Poultry Research Station, has been appointed professor of agricultural zoology and **Dr A. Care,** Rowett Research Institute, has been appointed professor and head of the Department of Animal Physiology and Nutrition, in the **University of Leeds.**

Dr G. Edsall, Harvard School of Public Health, has been appointed to the chair of microbiology, tenable at the London School of Hygiene and Tropical Medicine, and **Professor J. F. M. Middleton,** New York University, has been appointed to the chair of African anthropology, tenable at the School of Oriental and African Studies, **University of London.**

Dr David Evans, University of Sheffield, has been appointed to the new chair of computing in the Department of Mathematics, **Loughborough University of Technology.**

Professor R. H. Tuck has been elected dean of the Faculty of Agriculture and Food at the **University of Reading.**

Miscellaneous

Representatives of university departments and other qualified organizations and scholars are invited to apply for grants in aid of archaeological research to be carried out in the county of Somerset during 1972. The grants will be allocated from the **Maltwood Fund** by the Royal Society of Arts, and will total £1,000. Further information can be obtained from J. S. Skidmore, Royal Society of Arts, John Adam Street, Adelphi, London WC2N 6EZ.

Applications are invited by the **Lalor Foundation** for the 1972 postdoctoral awards, offered for research in certain aspects of mammalian reproductive physiology. This year preference will be given to work which is aimed at detection and exploration of dysgenic factors in ovum or foetal development, evaluation of the genetic factors involved and means towards their disposition. Research on non-traumatic cervical dilation and on various aspects of abortion will also be considered. Applicants may be of any nationality but should be under 41 years of age. The research may be undertaken at the applicant's own laboratory or elsewhere. Further information and forms of application can be obtained from the Lalor Foundation, 4400 Lancaster Pike, Wilmington, Delaware 19805, USA. The closing date for applications is January 15, 1972, and awardees will be notified on or before March 15, 1972.

Errata

IN the article "Science, Statistics and Society" by A. W. F. Edwards (*Nature*, **233**, 17; 1971), the last sentence of the second paragraph under the subheading "Causation, Correlation, Classification", page 19, should read: "Even though this is all the information I possess about you, it enables me to make a statement about your height, thus: the probability that you are between 5 feet 8 inches and 5 feet 8.5 inches tall is 0.08, if I take as my datum the fact that Englishmen are normally distributed in height with a mean of 5 feet 8 inches and a standard deviation of 2.5 inches".

IN the article "Inhibiting Effect of Some Antimalarial Substances on Glucose-6-Phosphate Dehydrogenase" by D. W. K. Cotton and A. H. M. Sutorius (*Nature*, **233**, 197; 1971), the second figure in the first column of Table 1 (NADP 0.002 M in buffer (ml.)) should read 0.01. Moreover, the name of the second author is incorrectly spelt in the contents list.

IN the News and Views article entitled "Fooling the Experts" (*Nature*, **232**, 442; 1971), the implication that the Basel Museum has purchased or is in possession of forged Etruscan paintings on terracotta is incorrect. The plaques in question only passed through the museum for examination when their authenticity was already in doubt. The Munich plaques are in a private collection. The Berne plaque is in the possession of the Archaeology Seminar of the University of Berne. There are genuine Etruscan plaques in the British Museum, the Louvre and the Villa Giulia Museum in Rome.

British Diary

Monday, October 25

Sensation and Neural Code (5.30 p.m.) Professor H. Hensel, University of London, in the Edward Lewis Lecture Theatre, Middlesex Hospital Medical School, Mortimer Street, London W1.

Tuesday, October 26

Air Pollution: How Dark the Shroud? (1.20 p.m.) Professor T. J. Chandler, University of London, in the Botany Theatre, University College London, Gower Street, London WC1.

Concepts of Structural Safety (5.30 p.m.) Dr K. O. Kemp, University of London, in the Engineering Theatre, University College London, Malet Place, London WC1.

The Chemical Engineer's Contribution to Air Pollution (7.30 p.m.) Mr C. J. Stairmand, Institution of Chemical Engineers, at the Unicorn Hotel, Prince Street, Bristol.

The Library, The Scientist and the Humanist (6 p.m.) Dr Robert Shackleton, University of London, in the Beveridge Hall, Senate House, London WC1.

The Wright Brothers: Inventors of the Aeroplane (1.30 p.m.) Mr C. H. Gibbs-Smith, University of London, at Queen Mary College, Mile End Road, London E1.

Treatment of Glass Surfaces for Composite Manufacture (6 p.m.) Dr B. E. Gillespie, Society of Chemical Industry, Plastics and Polymer Group, at 14 Belgrave Square, London SW1.

Wednesday, October 27

Discussion Meeting (5.30 p.m.) Society for Analytical Chemistry, Microchemical Methods Group, at Imperial College, London SW7.

Innovation in Industry—a Factor for Growth (6 p.m.) Institution of Electronic and Radio Engineers, at 9 Bedford Square, London WC1.

Relevance of Animal Feeding Trials to Human Dietary Requirements (6.15 p.m.) Dr K. L. Blaxter, Society of Chemical Industry, Food Group—Nutrition Panel, at 14 Belgrave Square, London SW1.

The Shape of Things to Come (5.30 p.m.) Professor E. R. Laithwaite, Institution of Electrical Engineers, at Savoy Place, London WC2.

The Teacher and the Taught: The Changing Roles in the Progress of Science (1 p.m.) Dr Frank Greenaway, Royal Institution, History of Science Discussion Group, at 21 Albemarle Street, London W1.

Thursday, October 28

Is There a Future in Computers? (7.30 p.m.) Mr R. J. Redding, Institute of Measurement and Control, at Stanley Palace, Watergate Street, Chester.

Photography One Hundred Years Ago (5.30 p.m.) Mr Arthur T. Gill, Royal Institution, Library Circle, at 21 Albemarle Street, London W1.

Physics in the Service of the Engineer (5.30 p.m.) Mr L. A. Thomas, Institution of Electrical Engineers, at Savoy Place, London WC2.

Solid State Detectors (2.30 p.m. discussion meeting) Society for Analytical Chemistry, Radiochemical Methods Group, at the Laboratory of the Government Chemist, Stamford Street, London SE1.

The Problem of Addressing New Display Materials (6.30 p.m.) Mr A. Colchester, Institution of Electronic and Radio Engineers, at the University of Cambridge Engineering Laboratories, Trumpington Street, Cambridge.

Friday, October 29

Curved Boundary Problems and Diffusion Approximations (5.30 p.m.) Professor H. E. Daniels, University of London, in the Chemistry Auditorium, University College London, Gower Street, London WC1.

Rutherford: a Century of Nuclear Energy (9 p.m.) Dr T. E. Allibone, FRS, Royal Institution, at 21 Albemarle Street, London W1.

The Forth-Tay Estuaries—an Environmental Assessment (10 a.m. symposium) Royal Society of Edinburgh, at 24 George Street, Edinburgh.

Type II Photocleave Reactions in Aromatic Thioesters (1 p.m.) Dr J. Wirz, Royal Institution, Photochemistry Discussion Group, at 21 Albemarle Street, London W1.

Saturday, October 30

Dinosaurs—The Terrible Reptiles (3.30 p.m.) Mr W. T. Blows, Inner London Education Authority, at the Horniman Museum, London Road, Forest Hill, London SE23.

Monday, November 1

Modern Food and Food Additives (6.30 p.m.) Dr D. W. Kent-Jones, Society of Chemical Industry, Food Group, at the Scientific Societies Theatre, 23 Savile Row, London W1.

Some Aspects of Drying Oils Technology (7 p.m.) Mr G. Hutchinson, Oil and Colour Chemists' Association, at the Queens Hotel, George Street, Hull.

Tomorrow's World in Telecommunications (7 p.m.) Institution of Electrical Engineers, at the Royal Star Hotel, Maidstone, Kent.

HOW TO BUY NATURE

Volumes start in January, March, May, July, September and November, but subscriptions may begin at any time.

The direct postal price per subscription is:

12 MONTHS* (52 issues per title)

	Surface Mail UK and worldwide	Airfreight U.S.A. & Canada
Nature (Friday)	**£14**	**$48**
Nature + Nature Physical Science	**£24**	**$83**
Nature + Nature New Biology	**£24**	**$83**
All three editions	**£29.50**	**$108**
Annual Index	**£1**	**$3**

* Rates for shorter periods *pro rata* (minimum three months)
(Charge for delivery by air mail on application)

OCTOBER 29 1971

Should Reproductive Biology be Encouraged?

FERTILIZING human eggs in the test tube and using prostaglandins as an abortion pill are spectacular ideas which have captured attention recently. But in the past year or so there have been advances in almost all aspects of human reproductive biology, although this work has been more in the nature of pinpointing the areas which can most profitably be exploited than in providing any definite answers. In this context, it seems likely that virtually all scientists will regard as timely the plans of the World Health Organization to inject considerable funds into some aspects of research on human reproduction. (An account of the programme will be found in *Nature New Biology* next Wednesday.)

Reproductive biology is, inevitably, a controversial subject and the promise to some, a threat to others, that research will make a revolution in social as well as in scientific thinking is reflected in last week's attacks by two Nobel Laureates, Dr James Watson and Dr Max Perutz, on the work of Dr R. G. Edwards and his colleagues from Cambridge. There is every prospect that, if successful, Edwards's work will lead to the development of procedures to allow human eggs to be fertilized *in vitro* and the embryos then to be reimplanted at an early stage of their growth. But although this technique may be able to overcome some forms of infertility, Watson and Perutz argue that it involves very great and quite unjustified risks of producing a defective embryo.

But whether or not what seems likely to develop into a campaign to stop such work is successful, other changes in reproductive biology are almost certainly in train. It will not be surprising, for example, if recent developments in distinguishing sperm carrying a Y-chromosome from those bearing an X-chromosome should lead to a ready technique for separating sperm according to whether they determine a male or female child. Coupled with the use of artificial insemination this finding implies that it may become possible to choose the sex of progeny.

Not everyone will agree on the value of advances of this nature, but research on embryogenesis itself has in general produced results which can universally be applauded. Immunological studies of foeto-maternal relationships, for example, have already proved their use in helping rhesus-positive babies to survive in rhesus-negative mothers. Indeed, histo-incompatibility studies on foetal development may lead to a better understanding of the processes which may go wrong (of which there seem to be many) in earlier embryogenesis. Studies on the presence of antigens on sperm may also be fruitful.

Spermatogenesis and the ovulatory cycle are ill-defined by comparison and it is this area of research which will benefit most from the expanded programme by which WHO hopes to increase understanding of the processes of human reproduction. The aim of the programme is to develop safe and effective methods for regulating human fertility. Research is planned on a broad basis. One reason for this is that WHO must take account of social mores which may mean that particular methods of contraception may not be acceptable in some countries. Another is that it is at present difficult to decide just what will prove to be the best ways of improving physiological contraception.

The decision is a sensible one to concentrate research on the basic processes which lead to sperm formation, maturation and transport and on the release, fertilization, implantation and early development of the egg. Even the stages of the ovulatory cycle are not at present known in much detail and just a slight increase in knowledge could cast a valuable light, for example, on what are the dangers of the rhythm method of contraception. A large part of the research will concentrate on the biochemistry of steroid action on tissues of the female reproductive system which certainly seems to offer the best prospects for improving contraception in the short term; fears about present contraceptive pills may be eased and better ones may be developed. The programme is also strong in that there will be centres which will conduct clinical trials of any possible fertility regulating agents.

It is all to the good that WHO seems to have decided that it is not sufficient just to conduct research and then to let the results look after themselves. An integral part of the programme is to help disseminate to other scientists the results which emerge from research on reproductive biology. There seems to be less certainty over just how this is to be achieved than there is about the research to be promoted but scientists will hope that a decision is taken and put into effect soon; plans for WHO to establish a Documentation Centre will no doubt be watched as an example of how communication can be improved in specific research areas.

How can WHO best support this ambitious programme of research? About $500,000 per year is at present spent by WHO on research in various aspects of human reproduction and this programme will continue. The new programme, however, with a projected income for its first year of nearly $7 million is likely to have more impact. Funds for the programme are being gathered from many sources and scientists will be anxious to see how well the plans work to organize research on rather closely defined lines.

Because of its international nature, particular problems must face WHO in organizing this programme. One of WHO's weaknesses is at the same time a strength; to be successful, the programme must take into account the susceptibilities of the member states of WHO in general and the funding agencies in particular. This means that justice must be seen to be done in apportioning funds to research institutions in different countries. The first consideration of the programme must, of course, be to ensure that the research supported is of proper quality. But it is no use providing answers if no one is willing to listen to them. The strength of WHO's approach is that any successes of a programme organized on such a wide basis will be likely to have an equally wide influence. Those who would judge the programme, therefore, should be duly sympathetic if at times it seems that it will take longer than it might to come up with the answers.

Poor Report for the Post Office

POSTS and telecommunications are no more suited to being part of the same enterprise than are ocean liners and aircraft. Yet history has lumped them together and organizations like the British Post Office must make the best of it. The best is none too good, as the report of the Post Office's first full year as a public corporation shows (*Post Office Report and Accounts, 1970–71,* HMSO, £1.50). So great were the losses on the postal services that the astonishing profits of £93.5 million on the telecommunications side left the corporation with a total profit of only £20.5 million, the lowest turned in since 1964–65.

To be sure, the seven-week strike of early 1971 hurt—all considered, it cost the corporation about £13 million—but the bulk of the postal loss of nearly £73 million was owed simply to the facts that it costs a great deal of money to hire people to carry messages by hand and that the public demands that its messages be carried cheaply. Mr Bill Ryland, the Post Office's new chairman, has said that increased postal charges are inevitable and the choice must be made between substantial price increases or lower quality service. He refused to be pessimistic about the future of the postal services while taking comfort from the health of the telecommunications service. But it is hard to share his pleasure in the telecommunications performance. What is so depressing about the corporation's first full report is the utter lack of promise of a sophisticated telephone system for Britain in the near future. While the vast profits from telecommunications are a great solace to the Post Office, they have not done much for the telephone subscriber. In the past year, the waiting list for new telephones has grown from 108,000 to 121,000, while the quality of the subscriber trunk dialling (STD) service deteriorated. The Post Office figures, always more conservative than those of the ordinary frustrated telephone user, concede that 8.7 per cent of calls failed because of faults in the system and calls made through the operator were also slightly more troublesome. In 1970–71 during the day it took the operator nearly 6.5 seconds to answer—the poorest record since 1966–67.

The Post Office admittedly is embarked on an extensive programme to expand and modernize the telephone service, and it is now spending about £500 million a year to make up for the mistakes—the Treasury's as well as its own—of the 1950s and early 1960s. Yet the report does not have cheerful things to say about the progress in modernizing telephone exchanges which are the bottleneck to any drastic improvements of the present system. Because so much existing equipment is of the old fashioned step-by-step Strowger variety, the Post Office had to spend £5.5 million in 1970–71 to buy more of the same, to keep the system running. Moreover, its independence as a corporation has not helped it find a solution to its chronic problem of the late delivery of equipment by the British telecommunications industry. In fact, in the past year, fewer orders were filled than the year before, and the average delay on exchange contracts was thirteen months, with the newer, more desirable crossbar exchange equipment even further behind schedule than the Strowger.

Perhaps the most worrying statements of the Post Office's report are "the relative cheapness of the telephone is creating a very heavy demand which is increasingly difficult to meet with present resources." "Waiting lists are bound to increase and service deteriorate until prices can be adjusted." What irks the Post Office is that while telephone calls are profitable, the average return on the rental of a telephone set is not. To put this right it would like to raise the rental—and drive some of those prospective customers away. The Post Office has not yet learned to concentrate on the golden eggs and forget the cost of buying the geese.

It is worrying that the Post Office misinterprets the demand for telephones. The waiting list refuses to diminish—not because telephone rentals are cheap but because the public is recognizing that telephone calls are cheaper and often superior (because they are instantaneous and two-way) as a form of communication than the letter. This recognition could be one of the Post Office's most valuable assets, if it chose to make it so. Because it is saddled with running both a postal service and a telephone system, why does it not argue publicly the advantages of using one over the other? British telephones are under-used and telephone calls on which the Post Office made so much profit last year were made from instruments which are used, on the national average, only twice a day. For that matter, the Post Office should be putting more effort into making cheap, throwaway telephones, and at least, insisting that telephone wires and outlets be installed in all new buildings.

The most essential task for the Post Office is to recognize that it is in the telephone service, not the moribund post, where the real emergency lies.

100 Years Ago

THE Inaugural Meeting of the Newcastle College of Physical Science on Tuesday last week was a great success. The Council decided unanimously, on the application of upwards of seventy ladies, to make no distinction of sex in the admission of pupils, placing all on a footing of exact equality. The total number of students admitted up to the time of the inaugural ceremonial, was fifty-one. In contrast to this we may note that last week the governing body of the University of Edinburgh rejected by a small majority Dr. Alexander Wood's motion, "That, in the opinion of this Council, the University authorities have, by published resolutions, induced women to commence the study of medicine at the University; that these women, having prosecuted their studies to a certain length, are prevented from completing them for want of adequate provision being made for their instruction; that this Council, without again producing any opinion on the advisability of women studying medicine, do represent to the University Court, that, after what the Senatus and Court have already done, they are at least bound in honour and justice to render it possible for those women who have already commenced their studies to complete them."

OLD WORLD

RESEARCH AND DEVELOPMENT

Constructive Advice

THE Institution of Professional Civil Servants feels that the British government should provide increased support for its industrial establishments so that Britain can compete on equal terms with other European countries. This advice is given by the IPCS to the Department of Trade and Industry as a contribution to the DTI's review of industrial research establishments (*The Role of the Government's Industrial Research Establishments in the 1970s*, IPCS).

The IPCS stresses that the advantages of such reviews are nullified if they are held too often and the institution feels that this has been the case recently—several establishments are now being reviewed for the third time in ten years. This almost continuous series of reviews coupled with changes that have placed some establishments under the aegis of four different departments in the same period has, in the view of the IPCS, led to uncertainty about jobs and prospects and a loss of morale.

The establishments now under review are the Laboratory of the Government Chemist, the National Engineering Laboratory, the National Physical Laboratory, the Safety in Mines Research Establishment and the Warren Springs Laboratory together with the United Kingdom Atomic Energy Authority establishments at Harwell and Risley. The IPCS sees a scope for increasing the work of these establishments, in particular by an increase in their contract work for individual companies. For this to be achieved, however, it will be necessary to increase the powers of the directors of the establishments so that they can exercise commercial judgment and develop the work as they see fit.

In his introduction to the report, Mr William McCall, general secretary of the IPCS, is possibly previewing Lord Rothschild's review of civil science when he calls for public research and development establishments to contribute more to the industrial and economic well-being of Britain. He also re-states the institution's view that these establishments should not diversify but should continue their work in basic long-term research.

The report comes out strongly against the idea that these establishments should pay their own way and it criticizes modern innovation theory, which holds that all industrial research should be self-sufficient. To substantiate this position Bell Telephone Laboratories Inc. is cited as a large company that has failed to keep its research and development self-sufficient. A plea is also made for more research and development resources to be made available to industry to supplement its own efforts and the IPCS points out that the industrial research establishments could well fit this bill.

The central theme of the report is that the present support of research and development by the government is biased towards defence, aerospace, electronics and nuclear power whereas industries that contribute most to the balance of payments—the mechanical and engineering industries for example—have been sadly neglected. The institution says that this imbalance should be corrected by providing more support for these industries at government establishments, provided however, that this is accompanied by a corresponding increase in research and development effort within the industry itself.

Perhaps the most important plea made by the IPCS is for increased support for industrial research and development so that Britain will not be handicapped in competition with other countries, in particular members of the European Economic Community. While emphasizing that support should not be increased merely because other countries are supporting both civil and military technology to a greater degree than Britain, the institution feels that British industry would be severely handicapped if there were no increase in support for industrial research and development.

EDUCATION

A-level Broadening

MORE schoolchildren are opting for A-level courses involving both science and other subjects, according to a report of the Department of Education and Science (*Statistics of Education*, 1, HMSO; £1.70). At the beginning of 1970 31.0 per cent of the 254,000 A-level pupils in schools in England and Wales were following courses comprising science subjects alone and a further 50.9 per cent were studying non-scientific courses; 18.1 per cent of the courses, however, contained both science and non-science subjects. In January 1969, the proportions were 31.0 per cent, 52.1 per cent and 16.9 per cent respectively.

During 1969 the total number of pupils of all ages rose by 2.4 per cent to 8.6 million, of which about 8 million were in maintained schools. The total teaching strength increased by 3.3 per cent and the pupil–teacher ratio dropped from 27.7 to 27.4 in maintained primary schools and from 17.9 to 17.8 in maintained secondary schools while in direct grant schools the ratio is 15.5.

The proportion of 15-year-old children continuing their school careers still shows large regional variations, but the figure for the north region, 46.9 per cent on January 1, 1970, compared with 44.9 per cent a year before, reflects a larger increase than that for the south-east region (63.8 per cent compared with 62.5 per cent). In 1966, 53.2 per cent of 15-year-old pupils in the south-east region stayed on at school beyond the statutory leaving age.

Reliving the Past

OVERHEARD at a reception at 21 Albemarle Street, London, last week: "I've not visited this place before; it's rather marvellous, isn't it?" Not such an extraordinary remark in the normal course of talk at a social gathering, but the speaker and the occasion gave it special meaning. With true British feeling for the past, the 172-year-old Royal Institution of Great Britain stepped back in history on October 20 and for three hours became once more the assembly rooms of London society. It had thought to ask to a party (no doubt with an eye, somewhat disguised, on some generous benefactions) as many descendants as could be traced of its founders, early proprietors and officers to meet some of the present members, to hear something of its history and functions today and to see its collection of archives and historic scientific apparatus.

Because so many distinguished and wealthy people directly associated themselves with the Royal Institution in its early days and supported it with subscriptions, it is not surprising that the list of descendants at the party read like an extract from *Debrett's Peerage* (although, of course, it is just these people who can most easily be traced). Few of the guests were practising scientists, although among them was the engineer Sir Richard Young, a descendant of Thomas Young who was one of the institution's first professors. The Percy family have long had an honourable connexion with the Royal Institution—the fourth, sixth, seventh and eighth Dukes of Northumberland were all presidents as was Lord Eustace Percy—and it was therefore fitting that the guest of honour was the tenth Duke of Northumberland, at present chairman of the Medical Research Council.

RESEARCH AND DEVELOPMENT

Summer Lightning

RESEARCH has begun into the possibility of providing Britain with an electricity transmission system of up to one and a half million volts. Since August, scientists at the Central Electricity Research Laboratories (CERL), using a gantry forty metres high and a Ferranti impulse generator capable of an open circuit output of 5.2 million volts, have been working on the basic problems of such a system.

The CEGB's new 400 kV supergrid is not yet fully commissioned but CERL has started work on ultra high voltage (uhv) because the time required to make a system operational means that research must be many years ahead of possible application. So far, each time a higher voltage network has been added, the voltage has roughly doubled —from 132 to 275 kV in 1950 and from 275 to 400 kV in 1960—but it has been suggested that the next step ought to be a trebling rather than a doubling of present levels—to 1,300 kV rather than 800 kV—because of the capital cost involved. It is also unlikely that demand will exceed the capacity of a 1,300 kV network in the foreseeable future.

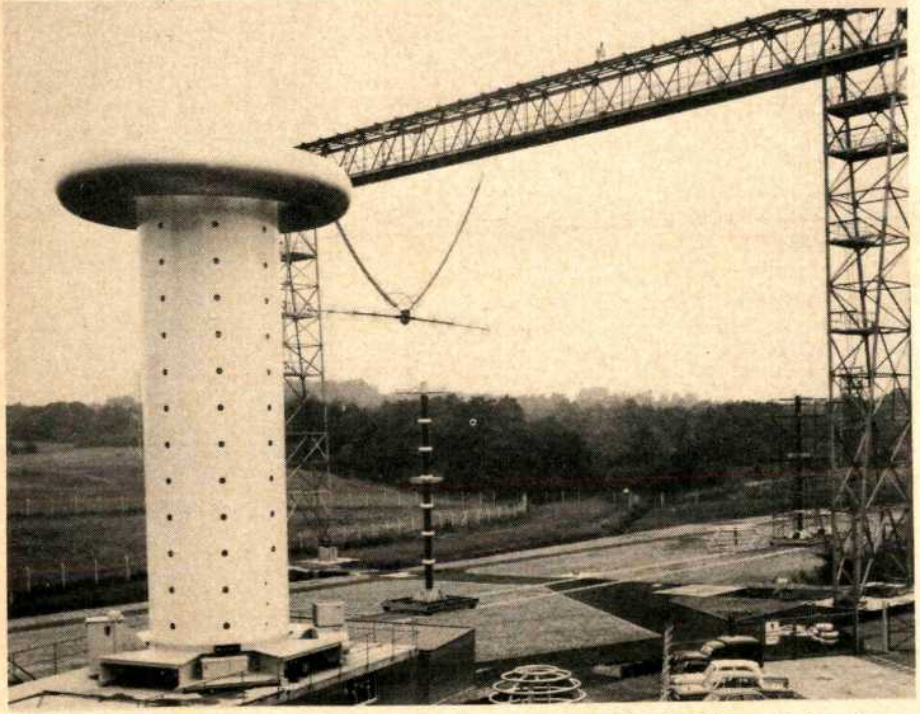
Work on the basic data for an 800 kV system has already been completed and CERL is at present trying to find insulators capable of resisting lightning strikes and the surges resulting from switching in a uhv system. With higher voltages there are ever increasing difficulties with insulation and it has been suggested that uhv transmission will prove impossible; at CERL, however, they are confident it can be done and hopeful that it will prove possible to carry uhv on a single circuit eight conductor bundle on towers no higher than those used at present.

The porcelain insulators at present under test have withstood simulated lightning strikes of up to 5 million volts without breakdown but switching surges, which can be expected to reach two and a half times the nominal rating of a transmission system, are tending to break down at about 2.25 million volts.

The facilities, sited at Leatherhead on the edge of the Surrey green belt, are the world's first completely all-weather uhv test facilities; they will be used in close cooperation with the CEGB's Brighton site where work will shortly begin on the other main problem of transmission, the reduction in insulation efficiency due to pollution. Salt in the atmosphere is the worst enemy, and the Brighton site, right on the coast, is ideal for studying this.

The capital cost of the Leatherhead and Brighton sites is about £500,000. Cost was one of the two main factors that resulted in outdoor sites—to put only the Leatherhead facilities indoors would have cost another £2 million. The other factor was the firm belief of Dr John Forrest, director of CERL, that a uhv grid will finally have to work outdoors so it might as well start that way. The power frequency tests, which need to be done indoors, can be accommodated later in the existing laboratories.

It is in fact doubtful if a grid of more than a million volts will ever be built. If the predicted 5.5 per cent per annum load growth rate for the later 1970s continues, then the present 400 kV network will be good for the next 20 years. Whether a 1,300 kV network (the likeliest voltage to be adopted over one million volts) will then be built will depend on the nature of power transmission by the 1990s; centralization resulting in fewer, bigger generating plants might well demand it, but a change in public attitudes to the siting of nuclear power stations near large towns, for example, would make it unnecessary. Whatever happens, uhv will not replace but only supplement the 400 kV network, and it is likely to be used only for the large-scale, long-distance transmissions from, say, the Midlands to London.



The CERL facilities at Leatherhead showing the Ferranti 5.2 million volt impulse generator and the test gantry that permits possible tower designs to be examined, and substation plant to be tested alongside. Eight conductors in a metre bundle are suspended from the gantry on the porcelain insulator strings.

SOVIET SCIENCE

Industrial Research

THE recent "Scientists for Industry" seminar held in Rostov-on-Don on October 13–15, 1971, has again brought to the fore the apparent lack of contact between research and development and industrial application in the Soviet Union. The Rostov seminar was devoted to problems of expanding research in technical colleges, in accordance with the dictates of industry, but background material published in the Russian press suggests the existence of a more urgent problem than was dealt with at the Rostov meeting.

Writing in Pravda (No. 278, 1971), Academician Aleksandr Ishlinskii, chairman of the All-Union Council of the Scientific-Technical Society of the USSR, stresses the need for the development of research and development laboratories within factories that could provide one of the chief links in technological progress. Unfortunately, in many establishments, they are poorly equipped outbuildings, unsuitable for serious research and many factory directors consider them to be second-class departments. Although specialists working in these laboratories are entitled to a similar salary to that of scientists in pure research institutes, very few directors are willing to implement such payments. Accordingly, there is a serious leakage of scientists from industry, particularly in the highly qualified classes.

A closer cooperation between science and industry was one of the principal resolutions of the Twenty-Fourth Party Congress held earlier this year, and the factory laboratory has often been commended as an excellent means of implementing this cooperation. But, without more attention and funds, they may act as a deterrent to cooperation.

SCIENTIFIC INFORMATION

One Step Nearer

First plans to help keep scientists and engineers in touch on a world-wide basis with the latest published work in their field have been approved at a UNESCO conference.

At a meeting in Paris earlier this month delegates from eighty-three countries and thirty-nine international organizations approved the recommendations made in October of last year to establish a World Science Information System, known as UNISIST (see *Nature,* **230**, 544 ; 1971).

The intention behind UNISIST is that it will help overcome the "information explosion" which has resulted in about two million scientific and technical articles being published each year in 70,000 specialized journals ; it will also make the work already published more easily available. UNISIST is the joint brainchild of UNESCO and the International Council of Scientific Unions, and its protagonists claim that its advantages are, first, that it is a world-wide organization that involves both governments and scientific organizations and, second, that unlike earlier plans for world-wide systems it is comparatively flexible, coordinating existing networks rather than establishing a new central organization. The chief problems that UNISIST faces are how to interconnect existing systems of information retrieval, whether conventional or computerized, and how to solve the problems of classification.

The recommendations that the conference discussed—and passed with only minor modifications—were the work of the UNESCO-ICSU committee that was created in January 1967, and final approval of the scheme now rests with the UNESCO general conference which meets in the autumn of 1972.

After the conference the chairman, Dr Harrison Brown of the United States National Academy of Sciences, said that there was "strong east–west cooperation" in the preparation for UNISIST. The French government is to establish a centre for an International Serials Data System, and Poland is providing an international training centre to help meet the shortage of information specialists. At present UNISIST is confined to science and technology, but it is hoped to extend it to cover the social sciences and humanities if the system proves successful.

A recommendation that allowance be made for UNISIST in the 1973–74 budget of UNESCO was passed to the director general, and although no figure was named, £750,000 to £1 million as recommended in October 1970, is thought to be a likely figure.

Whether UNISIST will ever function efficiently remains to be seen and doubts have been expressed as to whether UNESCO is the best body to run such an organization. The problem of accommodating the views and interests of all the countries involved is tending to produce more talk than action, and it has been suggested that intensification of the interchange of information between existing organizations might in the end prove more effective than the more ambitious UNESCO plan.

ARCHAEOLOGY

Old Boats, New Ideas

from a Correspondent

Boats excavated in Britain and dating from before the Norman conquest were discussed at an international symposium held earlier this month at the National Maritime Museum, Greenwich. The Ferriby boats (1600 BC to 800 BC) are the oldest yet found in northern Europe and were described by their excavator, Mr Edward Wright, who admitted that, apart from the last of the three excavations in 1963, the rescues had been archaeological disasters. The exception, Ferriby 3, is still being treated at Hull museum.

Although the ages of the Ferriby boats are quite different, they were found within a hundred yards of each other in the Humber foreshore and have unique common structural features. They are flat-bottomed with a hinged plank structure stiffened by poles pushed through cleats. Mr Wright suggested that these boats were relics from a prehistoric boatyard that had been located at the same site for centuries.

The rescue of the Ferriby boats has proved to be a cautionary tale. This time last year another ancient boat rescue was attempted, but under very different circumstances from Mr Wright's pioneering efforts. The preconquest Graveney boat was raised in seventy-three parts from a Kent marsh by a joint task force from the National Maritime Museum and the British Museum, and has since been the subject of a meticulous scientific examination.

The wealth of information now emerging from this painstaking work was sketched by the archaeological director of the project, Valerie Fenwick of the British Museum. Much is being learnt about trade contacts with Europe in the ninth century AD, the importance of the sea route as a highway between London and Canterbury, the relevance of the local saltworks to the battering which the boat received and so on. Several intriguing constructional details have also been deciphered ; it seems, for example, that the boat was built right side up in the open. Such information could not have been obtained without the most exhaustive study of the boat's timbers, involving the drawing of every mark on both sides of each fragment—a nine-month task.

One question raised at the symposium was how the Greenwich unit should deploy its still slim resources (see *Nature,* **233**, 226 ; 1971). Should it, as proposed by Mr Wright, deliberately excavate selected sites such as the sixth century BC Brigg raft still buried in a Lincolnshire brickyard or should it prepare itself for the next rescue? Ancient boats often emerge during land developments in Britain and, typically, have to be abandoned for lack of recording power and conservation facilities. Within weeks of the Graveney operation, for example, two boats of almost equal interest were found during cofferdam works in the Thames near the Mermaid Theatre. Although part of one of them was recovered, much valuable information was lost.

MUSEUMS

Keeping in Touch

History that is barely history is displayed in the Science Museum's new telecommunications gallery opened this week by Christopher Chataway, Minister for Posts and Telecommunications. The new gallery covers the development of electrical communication from the early nineteenth century to the days of colour television and a glimpse into the future is also shown.

The gallery, with an area of 10,000 square feet, provides about twice the area previously available for this collection, and is laid out on either side of a central avenue with the side bays going into particular aspects of the subject in greater detail. The north side of the gallery deals largely with line communications, the south side with radio, television and radar.

Among the more interesting exhibits are Cooke and Wheatstone's needle telegraph instruments, examples of the first transatlantic cables, and the equipment used in the Daventry test to prove the feasibility of radar in 1935, which is accompanied by a tape recording of an account of the experiment by A. F. Wilkins, who assisted Watson-Watts with the test. What is believed to be the only surviving example of the world's first centimetric radar equipment is included in the exhibition, as is the first commercially marketed video recorder.

Among the recent developments on show are a video cassette and a brief description of the possibilities of wave guides and optical fibres for carrying telecommunications signals.

NEW WORLD

New AEC Broom Begins to Sweep

by our Washington Correspondent

THE nuclear power industry is by now used to accusations that it is abusing the natural environment and endangering the health of countless Americans. Mere accusations that its quality control and safety standards are not all they might be would, in normal circumstances, scarcely merit a single raised eyebrow, but last week these accusations caused considerable consternation in the nuclear industry, for they were made by James R. Schlesinger, the new chairman of the Atomic Energy Commission. And, to rub salt in the industry's wounds, Schlesinger added that the nuclear companies need not look to the AEC to fight their battles, for the commission's most important job will be to protect the interests of the public.

These remarks were made not to an appreciative audience of environmentalists, but to representatives of the nuclear industry itself who listened with growing alarm to what Dr Schlesinger had to say in his first public speech. The remarks have been widely interpreted as marking a fundamental shift in the AEC's policies, but what they mean in effect is that the Atomic Energy Commission is fully prepared to stand by the new regulatory procedures set up in response to the appeals court decision on the Calvert Cliffs reactor (see *Nature*, **233**, 85; 1971). In a sense, Dr Schlesinger will be seeking during the next few years to build up public confidence in the AEC's power to regulate the nuclear industry, and in so doing, he is likely to help the cause of nuclear power much more effectively than by siding with the nuclear industry.

The burden of Dr Schlesinger's message was that the nuclear industry has now grown past the stage at which it needs to be nurtured by the AEC, and that it ought now to be capable of standing on its own feet. "From its inception, the Atomic Energy Commission has fostered and protected the nuclear industry," he said. "Looking back, one can, I think, say that this was the right policy for that historical epoch . . . but that industry should now be on a self-sustaining basis. Those of you who regard the response to Calvert Cliffs as indicating a climatic change in the relationship between the industry and the AEC could well be right, though perhaps for the wrong reason. The move toward greater self-reliance for the industry had a certain historic inevitability."

The AEC has been consistently criticized in the past for allowing nuclear power companies to get away with substandard engineering and in consequence the purchasing utilities have bought plants which are unduly susceptible to breakdown and poor performance. But in future, if Dr Schlesinger lives up to the promises made in his speech, the AEC will tighten its control considerably over important but unglamorous engineering details. "The AEC's role is . . . primarily to serve the public interest," Dr Schlesinger told his audience, and "those engineering details are the heart of the problem". The AEC will need to be assured that piping is of the highest quality, that pumps work and that valves are properly designed. "Those in industry who have chided us —quite properly—about the AEC regulatory process know full well that you have reason to blush regarding some of these aspects of quality assurance," Dr Schlesinger told his audience.

But the AEC will not expect to fight all the battles for the purchasing utilities for ever, for Dr Schlesinger told them they should acquire the technical expertise and trained personnel to make sure that they receive good value for their money from the builders of power plants. If the utilities acquire this expertise, it will help "to avoid power disruptions, to insure that plants can and will be properly maintained and, among other things, to avoid relying on the Atomic Energy Commission to perform this critical task".

Much of what Dr Schlesinger had to say was a bitter pill for his audience to swallow, and the nuclear power industry could perhaps be excused for choking on some of his suggestions, if only because they are reminiscent of many of the charges levelled at the industry by some of its more vocal opponents. Indeed, Dr Schlesinger had more than a good word to say for the environmentalists who have pitted their armour against the industry in the past. "A number have bad manners," he said, "but I believe that broadside diatribes against environmentalists to be not only in bad taste but wrong. I believe that we shall receive from responsible environmentalists considerable assistance in resolving our present difficulties." Dr Schlesinger refused even to be drawn into the argument over whether or not society ought to curb its appetite for nuclear power, saying that "it would be inappropriate for the Atomic Energy Commission to take a position on this issue".

In a sense, the AEC has already demonstrated to the nuclear industry its new role, for in spite of great industrial pressure to appeal against the Calvert Cliffs decision, the AEC chose instead to amend its regulations. Dr Schlesinger pointed out that the new regulations present no insuperable difficulties, and "while they are tough, they are workable". He chided the nuclear industry for advising the AEC to evade the court mandate, saying "it is not the AEC's responsibility to ignore on your behalf an indication of Congressional intent". There is a clear option open to the industry if it believes the new regulations to be too harsh, and that is through the courts. There will evidently be nothing to be gained by complaining to the AEC itself.

Finally, Dr Schlesinger set about dismantling a popular misconception. "It is not the responsibility of the AEC to supply power," he said, and he went on to infer that those who have criticized the AEC for fostering the demand for electricity would do better levelling their complaints at the utilities themselves. "The AEC does not sell power reactors. We are a bystander, sympathetic I trust. The selling of power reactors is a concern of the vendors: the decision to buy that of the utilities."

Set against remarks made by Dr Glenn Seaborg, Dr Schlesinger's predecessor as chairman of the AEC, Dr Schlesinger's speech marks a change of attitude, if not of policy. In a speech to the International Platform Association, in July, for example, Dr Seaborg had little hesitation in jumping into the debate about society's need for power, and he spent much of his speech extolling the virtues of nuclear power as opposed to other forms of energy.

Why did Dr Schlesinger choose to hit out so strongly and controversially in his first public pronouncements as head of the AEC? Perhaps one answer lies in his statement that "it is to industry's long run advantage that the public has high confidence that the AEC will appropriately perform its role".

SPACE

Martian Accord

by our Washington Correspondent

THE expected simultaneous arrival in orbit around Mars of NASA's Mariner-9 and the USSR's Mars 2 and 3 probes next month will set the stage for a far-reaching agreement on space matters between the United States and the Soviet Union. The fruit of a series of meetings in Moscow in August, the agreement provides for exchange of information between NASA and the Academy of Sciences of the USSR almost as soon as the information is relayed back to Earth from the Mars spacecraft.

This exchange of information will, however, be merely the first tangible evidence of a number of agreements hammered out between NASA and the Academy of Sciences of the USSR in recent months. The agreements, the terms of which have recently been made public by NASA, provide for cooperation on space activities ranging from planetary exploration to monitoring the Earth's environment by satellite.

The exchange of Mars data will allow particularly interesting phenomena to be studied by the spacecraft of both countries, and it will also allow some areas of Mars to be studied simultaneously by two probes. The idea is that experimental data will be relayed between NASA and the Academy of Sciences of the USSR by telex, by giving the nature, time and location in agreed Mars coordinates of phenomena such as changes in the colour of the Martian surface, or movements in the atmosphere. It is hoped that this exchange of information will be followed by a bilateral discussion of the preliminary results of the missions in March next year, and by a deeper review of the results a year later.

If this agreement is successfully carried out, it could pave the way for implementation of the other agreements reached in Moscow last August, and it could also help the negotiations aimed at development of compatible docking systems on US and USSR spacecraft (see *Nature*, **233**, 160; 1971). The fount from which this new accord springs is a meeting on space cooperation, held jointly by NASA and the Academy of Sciences of the USSR in January this year, as a result of which a number of joint working groups were set to work on areas thought to be particularly ripe for cooperative efforts. Recommendations from three of these working groups have recently been approved by NASA, and they provide for a variety of means for sharing information, and even for joint planning of some projects.

As far as exploration of near Earth space is concerned, one working group recommended that joint seminars be held whenever the need arises, to analyse data and coordinate programmes. On a slightly more practical note, the working group also suggested that a study be made of the possibility of transmitting magnetometer data from a USSR ground-based station, to the proposed US ATS-F geostationary satellite. The idea is that these data would then be relayed back to Earth with data from an on-board magnetometer and used for correlating magnetic variations in space with those on the ground.

The working group also recommends the holding of bilateral discussions on the results, objectives and strategy for planetary exploration and, in addition to sharing information on the Mariner and Mars 2 and 3 probes, that by the end of the year, the USSR will provide NASA with 700 time-of-flight data points for Venus, in exchange for about 900 post-1965 data points on Mars. On lunar exploration, representatives of the USSR will attend the Lunar Science Conference in Houston in January, and the working group has suggested that a lunar conference be held in the USSR in February or March 1973 so that future lunar exploration can be discussed. The agreement also provides for the exchange of photographs and maps of the lunar surface, and finally, the working group recommends that the two organizations continue to discuss the "possibilities of complementary lunar exploration activities".

To work towards a closer accord on environmental monitoring, NASA and the Academy of Sciences of the USSR have agreed to conduct remote sensing of designated sites in the US and the USSR either by satellite or by aircraft, and to exchange the results in the form of technical reports. The agreement also provides for exchange of infrared temperature measurements taken over the oceans, so that these measurements can be compared with actual measurements taken on board ships, and both organizations have agreed to work towards cooperation on programmes designed to monitor sea surface roughness, ocean biological productivity and sea ice conditions.

Finally, on meteorology, NASA and the USSR Academy of Sciences have agreed to exchange technical notes on temperature sounding by satellite, and to organize a joint experiment on temperature sounding over Western Europe for 1973–74. One NASA official said last week that the working group recommendations have all been accepted in principle by NASA and the Academy of Sciences of the USSR, but the practical details still need to be sorted out. What happens in orbit around Mars could therefore be important to future cooperation on all kinds of space activities.

COMSAT

For Services Rendered

by our Washington Correspondent

THE Communications Satellite Corporation (Comsat) has been undercharged to the tune of $6.1 million by the US government for the launching of communications satellites between 1965 and 1969, according to an investigation carried out by the General Accounting Office. The GAO recommends that $31,000 should be recovered from Comsat, and that the basis on which the company should be charged for all the Intelsat IV launches (including the first launch last January) should be changed so that all the costs are included. NASA and the Air Force (which launches satellites for Comsat) are in general agreement, but the Department of State and Comsat itself do not see eye to eye with the GAO's recommendations.

Chief reasons for the undercharging were deficiencies in the accounting methods used by the Air Force and an agreement between NASA and the Department of Defense to the effect that Comsat would not be charged for research and development associated with the launches. The upshot was that Comsat entered into an agreement with NASA which left the US Government paying for both the depreciation and the research and development associated with the launching of Intelsat satellites. The GAO report suggests that the basis on which Comsat was charged for the launching of Intelsat I, II and III cannot now be changed, but the company was not charged for at least $31,000 worth of services covered by the agreement. The GAO believes that this amount should be recovered, and that the agreement to launch Intelsat IV satellites should be renegotiated to include full launch costs.

The issue is complicated for several reasons. First, the Air Force, which launches the satellites, charges NASA, which in turn charge Comsat for the launch and support services. The basis for these bills is set out in agreements between NASA and Comsat, but the Intelsat IV agreement includes a clause to the effect that changes in the Air Force charges may be renegotiated. On the other hand, Comsat is the managing company for the International Telecommunications Satellite Consortium—a group of 80 nations interested in telecommunications satellites — which has had some severe internal problems during its first few years of existence.

The Department of State is therefore chary of causing an international dispute by an unseemly wrangle over $31,000.

The GAO argues that special services provided by the US government should be charged at their full cost, and that Comsat is now a viable commercial concern which ought to pay its full share (it recently reported a net income for the first quarter of 1971 of $4,978,000). A Comsat official said last week that the GAO report is being considered by the company, and pointed out that $31,000 should be compared with the $30 million it costs to launch each satellite. Comsat would, however, resist any attempt to change the basis for charges incurred by the launching of Intelsat IV satellites.

TUBERCULOSIS

Ribicoff lashes CDC

by our Washington Correspondent

SENATOR Abraham Ribicoff has, in the past few weeks, shown little respect for the agencies which he regulated when he was Secretary of Health, Education and Welfare in 1961–2. Two weeks ago, he lashed the NIH's Division of Biologics Standards for allegedly relying on dubious techniques for testing influenza vaccines, and last week the Food and Drug Administration and the Center for Disease Control were the subjects of his wrath for the part they played in the mass TB immunology programme on Capitol Hill last year, during which two people died of hepatitis. Senator Ribicoff's chief complaint is that the Center for Disease Control, which supervised the programme, gave 300 mg single doses of isoniazid—the drug commonly used for treatment and prevention of tuberculosis, instead of the usual treatment of three separate 100 mg tablets.

Based on an investigation conducted by the General Accounting Office, Senator Ribicoff's allegations were made in a stinging speech delivered in the Senate. He said that in 1964 the Center for Disease Control asked for permission to start investigational use of a 300 mg tablet of isoniazid. Under FDA rules, the centre should have supplied information derived from animal tests, and an outline of the planned investigation. "CDC supplied virtually none of this information to the FDA," Ribicoff claimed, "Instead, the CDC doctors started an accelerated experimental programme on a wide range of human subjects." Part of this experimental programme included the mass treatment of Capitol Hill employees last year after some cafeteria staff had contracted tuberculosis.

A spokesman for the FDA last week, however, although admitting that the agency "did not push the CDC for its experimental results", suggested that the CDC's action in the Capitol Hill programme simply followed accepted medical practice. He also pointed out that the two people who died from hepatitis during the programme showed symptoms of the disease eight months after they began taking the drug. Nevertheless, the latest bulletin of the FDA points out that it has recently changed the labelling on isoniazid to the effect that the drug should not be used if hepatic disease is suspected, and that the patient should be closely monitored. Alongside the announcement, however, the FDA bulletin contains an editorial by Gordon M. Meade, formerly medical director of the American Thoracic Society, who points out that "isoniazid remains a powerful and very effective antituberculosis agent which merits continued therapeutic and prophylactic use even though liver dysfunction can be associated with its use".

Short Notes

by our Washington Correspondent

Fort Worth

A CONFERENCE committee set up to decide the future of the Public Health Services Hospitals in general, and the drug rehabilitation centres at Lexington in Kentucky and Fort Worth in Texas in particular, reached deadlock on October 7. The Department of Health, Education and Welfare, frustrated in its plans to transfer the Fort Worth facility to the Bureau of Prisons, seized its chance and ordered the facility closed and all patients sent back for treatment in their home communities within twenty-four hours. The result: Congress was presented with a *fait accompli,* and, according to Mr James C. Wright, Texas representative in the House of Representatives, at least half of the ninety-two addicts discharged were taking drugs again before the weekend was finished.

The trouble was that in its desire to transfer the facility to the Bureau of Prisons, the Department of Health, Education and Welfare overlooked the fact that October 8 was a Friday. Consequently, many of the addicts could not be reached by representatives of their local rehabilitation centres for nearly three days, and not surprisingly many returned to the habit—none had been under treatment for more than four months. Mr Wright, who set his committee investigators to look into the fate of the addicts, found one pushing drugs in New Orleans; another smashed up a car and was jailed for speeding and was later found to be high on drugs. Mr Wright described HEW's actions as "a flagrant breach of good faith with Congress". He said, "I was stunned that a Federal agency would stoop to using drug victims as pawns in a power play to thwart the will of Congress."

Science in School

FIGURES released this week by the National Science Foundation show that the number of schoolchildren in public schools opting for science subjects increased by a factor of 2.5 between 1948–49 and 1969–70—faster than total enrolment which for grades 9 to 12 increased 2.3 times over the same period. "The steady proportional growth of enrolments in such basic core courses as introductory algebra, introductory geometry, biology, and chemistry indicates a basically healthy state of science interest at the high school level," the NSF claims. The figures released, however, unfortunately include no discussion of recent trends which may reflect the growing disillusionment with science and technology in the present state of concern about the environment, and the NSF's optimism is therefore difficult to question. One fact which mars the optimism is that enrolments in physics have lagged dramatically during the past two decades—in 1949, 28 per cent of the 12th grade were enrolled in physics courses, but in 1970 the percentage had dropped to 18.

Table 1 Enrolment in Selected Science and Mathematical Courses in Grades 9 through 12 in US Public Secondary Schools as a Percentage of Total Enrolment in the Grade in which the Course is Usually Offered

Course	Grade in which usually offered		Per cent

NEWS AND VIEWS

Cholinergic Receptor Sites in Muscle

THE transfer of excitation from nerves to muscle fibres is the most thoroughly studied example of chemical transmission in the nervous system. A great deal is now known of the mechanisms responsible for the synthesis, storage, release and subsequent metabolism of the transmitter substance, acetylcholine, which is involved in the transmission of impulses at neuromuscular junctions. Until recently, much less was known of the post-junctional receptor mechanisms which are activated by acetylcholine to cause excitation of the muscle fibres. The exploitation of the extraordinary properties of the substance α-bungarotoxin, however, seems likely to lead to rapid progress in understanding the nature of such receptors.

Bungarotoxin is a protein, of molecular weight 8,000, which can be isolated from the venom of the Formosan snake *Bungarus multicinctus*. The protein seems to be the affinity label *par excellence* for acetylcholine receptors in vertebrate muscle, and in analogous structures such as the electric organs of electric fish and eels. The snake seems to possess a "receptor probe" molecule with near ideal properties, because bungarotoxin seems to bind with extremely high affinity and almost complete specificity to muscle and electric organ cholinergic receptor sites.

By using bungarotoxin labelled with radioactive iodine-131, it has already proved possible to perform preliminary studies towards the isolation and purification of cholinergic receptor molecules from electric organ tissue (Miledi, Molinoff and Potter, *Nature*, **229**, 554; 1971). In this issue of *Nature* (page 599), Miledi and Potter describe the application of bungarotoxin to studies of cholinergic receptors in amphibian and mammalian muscles. The extensive pharmacological studies of Chang and his colleagues in the past decade had shown that bungarotoxin is a powerful cholinergic antagonist in vertebrate muscles. Miledi and Potter confirmed that the exposure of frog or rat nerve-muscle preparations to low concentrations of bungarotoxin (1 μg/ml.) abolished neuromuscular transmission within a few minutes. The action of the toxin was irreversible, because no recovery of transmission or responses to applied acetylcholine occurred even after washing such preparations for up to eight days.

When nerve-muscle preparations were exposed to ^{131}I-labelled bungarotoxin, some label became firmly bound to the muscles; this binding was saturable and reached plateau levels within about two hours. If the binding of bungarotoxin is specific for cholinergic receptors, it should occur only on those areas of the muscle surface which underlie nerve terminals, because it is well known that non-innervated regions of muscle are virtually insensitive to acetylcholine. In diaphragm muscle, the innervated regions of muscle can be fairly simply dissected from non-innervated regions, because the neuromuscular junctions of adjacent muscle fibres are quite precisely aligned in such preparations. When such dissection was performed it was found that more than 90 per cent of the bound labelled bungarotoxin was present in the innervated region of muscle, which represented only one sixth of the muscle weight. This high degree of localization of toxin binding to innervated regions of muscle speaks strongly in favour of the specificity of such binding to receptor sites.

Assuming that labelled bungarotoxin does bind with such specificity, then the amount of toxin bound under saturating conditions can be used to estimate the number of cholinergic receptor sites in various muscles. Using this approach Miledi and Potter obtain values of 10^9 sites per neuromuscular junction in frog sartorius muscles, and between 1 and 4×10^7 sites per junction in mouse and rat diaphragm muscles. The dimensions of the area of muscle membrane underlying nerve terminals are known from previous studies so that the density of receptor sites in frog sartorius junctions can be estimated as approximately 100,000 per square micron of membrane. The recent neurophysiological studies of Katz and Miledi (*Nature*, **226**, 962; 1970) suggest that the depolarization of the muscle membrane which occurs in response to nerve stimulation is composed of many virtually simultaneous "single shot" activations of cholinergic receptors. Katz and Miledi have estimated that each individual receptor activation or "single shot" event gives rise to a depolarization of 0.22 μV amplitude; to cause the overall depolarization observed in response to a single nerve impulse would require approximately 600,000 such events in the frog sartorius muscle. Even if as many as ten receptor molecules were involved in each "single shot" event, the calculated receptor population at frog sartorius junctions of 10^9 suggests that only a minute proportion of these receptors are activated by each nerve impulse.

The examination of bungarotoxin-^{131}I binding in muscles which had been surgically denervated has also yielded important information on the changes in cholinergic receptors which occur in such preparations. Previous studies by Miledi (*J. Physiol.*, **151**, 1; 1960) and by Axelsson and Thesleff (*J. Physiol.*, **147**, 178; 1959) have shown that a curious spread of acetylcholine sensitivity occurs in muscles which have lost their normal innervation. In normal muscles only the region of membrane directly underlying the neuromuscular junctions responds sensitively to applied acetylcholine; denervation is followed by a gradual spread of this area of acetylcholine sensitivity radially over the muscle membrane, so that after several weeks the entire surface of the muscle membrane may become highly sensitive to externally applied transmitter.

Using labelled toxin, Miledi and Potter have now confirmed that a large increase in toxin binding sites occurs after surgical denervation of muscles; increases of up to twenty times the normal binding were observed three weeks after denervation. Furthermore, by dissection of innervated and non-innervated regions of diaphragm muscles it was found that toxin binding sites became uniformly distributed along the muscle fibres in the denervated preparations. Regions of muscle which are not normally innervated showed increases of up to 200-fold in their ability to bind bungarotoxin after denervation. When denervation was effected by crushing the motor nerves, damage to the muscle innervation is quite rapidly reversible, as the nerves will regenerate to re-innervate the muscle fibres within a few weeks. When such re-innervation occurs the changes in acetylcholine sensitivity of denervated muscles are reversed, and the preparations revert to their previous state of precisely localized acetylcholine sensitivity. Miledi and Potter have found that the spread of toxin binding sites is also reversed when denervated muscle preparations become re-innervated after nerve crush—showing again that the behaviour of bungarotoxin exactly parallels the inferences previously drawn about cholinergic receptor sites from neurophysiological evidence.

A curious and still mysterious aspect of the results reported by Miledi and Potter concerns the differences which seem to exist between the binding of bungarotoxin and curare to muscle receptors. Curare has for long been known as the classical antagonist drug for muscle acetylcholine receptors. Small concentrations of *d*-tubocurarine completely abolish neuromuscular transmission and cause total block in responses to applied acetylcholine. When curare was used in the presence of labelled bungarotoxin, however, it prevented the binding of only 50 per cent of the toxin, even when high concentrations of *d*-tubocurarine were used. The suggestion that some 50 per cent of toxin binding might be unspecific seems to be ruled out by the precise localization of toxin binding sites at neuromuscular junctions. It would seem therefore that curare can interact with only half of the receptor sites present in muscle; the nature of the difference between the curare-sensitive and insensitive sites remains obscure.

The results obtained by Miledi and Potter throw some light on the phenomenon of receptor desensitization. Previous studies have established that prolonged exposure of muscle preparation to high concentrations of acetylcholine leads to a long lasting decrease in the ability of the muscles to respond to acetylcholine. Such desensitization could be attributable to a variety of causes. The receptor mechanism, for example, might retain the ability to bind acetylcholine, but failure might occur in the subsequent events leading to increased membrane permeability to ions. Miledi and Potter have now shown, however, that after prolonged exposure to acetylcholine the binding of labelled bungarotoxin is reduced by as much as 80 per cent. This suggests that the desensitization phenomenon involves some persistent change in the conformation of the receptor molecules.

Finally, Miledi and Potter report that the use of labelled bungarotoxin may be applied to muscle receptor isolation, as previously reported for the electric organ. Labelled toxin can be used to follow the isolation and purification of the toxin-binding substance. Preliminary experiments show that the labelled material can be solubilized from muscle preparations by the use of 'Triton X-100', and that the solubilized material can be further disaggregated by sodium dodecyl-lauryl sulphate.

EVOLUTION

Natural Selection and Industrial Pollution

from our Population Genetics Correspondent

ONE of the problems for many species of animals and plants is how to adapt to man's rapidly changing industrial environment. Until about 1800, man can have had only a slight effect on the environments of most species. Organisms evolved in response to the evolutionary changes of others and the generally slow changes of the physical environment. There was usually time for even the slowest breeders to adapt themselves to new conditions. But in the past few hundred years many species have become extinct and many more are threatened. This is a direct effect of man's activities.

An animal can adapt itself to a new environment provided the change is not so drastic that a large proportion of the population is eliminated by selection and not replaced by reproduction. Genetic variations in fitness are also necessary, of course, if fitness is to increase in the new environment. For an animal with a long generation time, the environmental change, if it is very rapid, may have gone so far in a single generation that the population cannot adapt to it. But an organism that produces many generations in the same period will easily be able to adapt to the relatively slight changes that take place in each of its brief generations. This is the problem with the use of pesticides. The pests are often organisms such as insects which produce a new generation every few weeks and they can usually adapt to the increasing quantities of insecticides the farmers throw at them. But the larger predators, such as birds of prey with their long generation times, are in danger of being completely eliminated. When predators are eliminated, their prey, if they are highly resistant to the pesticide, may increase rapidly and produce population explosions because there may be nothing but disease and lack of food to check them. The biological environment thus becomes very unstable and greater and greater use of an increasing variety of pesticides is necessary to control the pests.

Pesticides are merely the most drastic of the selective agents produced by man. Many other selective agents are produced unconsciously as a byproduct of the industrial society. The evolution of industrial melanism in various moths is a well known example of selection favouring a dark variety of the species which will escape the attentions of predators in industrial environments. The selective forces in favour of the melanic are quite strong—of the order of a 50 per cent advantage to the melanic form. The value of smoke abatement is demonstrated by the almost immediate decline in the frequency of the melanics where smoke control zones are introduced (Clarke and Sheppard, *Proc. Roy. Soc.*, B, **165**, 424; 1966).

Many other species of insect show examples of melanism, for example, the two-spot ladybird (*Adalia bipunctata*). The melanics, which are black with red spots, are found in high frequency in industrial areas. But the melanism cannot have evolved by selection by predators, for ladybirds are poisonous and are rejected as food. Presumably the melanics are simply more tolerant of the toxic elements in industrial pollution. Creed (in *Technological Injury*, edited by J. Rose; Gordon and Breach, 1969) certainly found a very close correlation between the frequency of melanic ladybirds and smoke concentration. In the latest issue of *Evolution* (**25**, 290; 1971) he describes the results of a survey of the frequencies of melanic ladybirds in various parts of Birmingham and compares them with their frequencies of a few years before.

In some areas of the city, the frequency dropped by as much as 50 per cent in four years. On average, from 1962 to 1967, the frequency of the black ladybirds dropped from about 45 per cent to 25 per cent. In the same period, as a result of the introduction of smoke control zones the level of smoke pollution fell by 40 per cent. There is no direct proof that selection for black ladybirds is caused by smoke pollution, but the circumstantial evidence is very strong.

Assuming that smoke abatement is responsible for the decline in the melanic ladybirds, it is possible to work out from Creed's figures the selection against the melanics in the less polluted environment of Birmingham. If about eight generations have passed since the introduction of smoke control zones, the selective coefficient against the melanics comes out at about 0.12. This means that the melanics suffer a mortality of 12 per cent over and above that of the normal, non-melanic ladybird in the new environment.

Although these selective forces are much smaller than those produced by pesticides, it is important to remember that they are the selective forces involved in the change back to a more natural environment. The original selection for melanism may have been much more drastic. Ladybirds can obviously adapt themselves to these industrial changes without much difficulty. Birds and mammals may not find it so easy. If the partial abatement of one aspect of industrial pollution can have such selective effects in thus raising the fitness of the normal red form of the ladybird, there can be no doubt of the benefit of the abatement of pollution in general in improving the natural environment. The leading article in the issue of *Nature* for October 15 (**233**, 437 ; 1971) made the point that pesticides have brought great benefits to man, as well as a certain amount of harm to the environments of many species: on balance "DDT may be good for people". Smoke and other avoidable effluents seem to offer no worthwhile benefits in compensation.

ANIMAL BREEDING

Keeping Fossils Alive

from a Correspondent

For ten years an *ad hoc* group of biologists has laboured to gain support for a scheme that would systematically conserve breeds of farm animals that are in danger of extinction. Several breeds of cattle, sheep and poultry were kept in a "gene bank" at Whipsnade (*Nature*, **202**, 131 ; 1964) but these had to be dispersed when the Zoological Society of London needed the space.

In spite of lack of funds, some of the livestock were taken over by the Royal Agricultural Society of England at its National Agricultural Centre, Kenilworth. The organizing group became a working party under the auspices of this society, and it organized a conference on rare breed survival on October 15 to draw attention to the problem.

Mr W. Longrigg (Chief Livestock Adviser, MAFF) outlined the decline of breeds, which has chiefly been caused by changes in demand. Belatedly, geneticists are beginning to realize that the scientific approach to animal production should not be governed by current profitability, but by the need to maintain variability for future selection.

But economic value is only one aspect of the case for preservation which was presented by Dr P. A. Jewell (University College, London). He pointed out that every breed, like a wild species, represents unique genetic material of importance in archaeological, historical and scientific research as well as being a living museum of educational value. Once lost, a breed cannot be re-created. Dr Jewell described work in which bones from surviving primitive breeds such as the Soay sheep had been used in archaeological comparisons, and outlined research on the blood types of cattle in which primitive survivors had widened the range of study. He pointed out that Darwin used observations on domestic animals in his theory of evolution.

Dr M. L. Ryder (Animal Breeding Research Organization, Edinburgh) showed how survivals of sheep from prehistory, the Middle Ages and the nineteenth century had enabled a study of their development, and particularly of fleece evolution, to be carried out.

Professor J. C. Bowman (University of Reading) gave the results of a survey carried out in 1970 to ascertain the exact status of breeds. It was found that some well known sheep breeds had declined alarmingly to numbers lower than other breeds already designated "rare", for example, the Wensleydale (260) and Wiltshire (400) compared with the "rare" white-faced woodlands (700). He considered that it should be possible to keep a breed viable with as few as fifty individuals, provided the ratio of males to females was kept much higher than in normal husbandry. But two breeds of pigs (Tamworth and middle white) had fewer than the critical number of ten males.

The papers created considerable discussion and comment and it was decided to establish a society for the preservation of rare breeds, the functions of which would include the registering of animals, exchange of stock and technical advice. Further information can be gained from the Royal Agricultural Society of England.

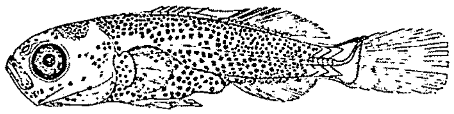
GOBIES

Two Species or One ?

from our Marine Vertebrate Correspondent

The diminutive goby *Lebetus* has attained some degree of distinction among European fish as the smallest vertebrate in the fauna, a claim which has even ensured it a place in the *Guinness Book of Records* (although parts of the entry are sadly erroneous). Now, however, its interest is reinforced by a remarkable uncertainty as to the number of species within European waters.

Neclâ Demir and F. S. Russell have reported recently (*J. Mar. Biol. Ass. UK*, **51**, 669 ; 1971) that two forms of *Lebetus* postlarvae were distinguished in the collections of young fish at the Plymouth Laboratory. These two types of postlarvae show certain differences in the concentration of pigment cells, and also show quite distinct differences in fin development at comparable sizes. Thus in one form the dorsal and anal rays are well defined when the young fish is 5.0–5.5 mm long but are only just noticeable in the other form at this length. Pelvic fin development also shows similar differences, and even more significant are the numbers of vertebrae, 25–26 in one form, 27–29 in the other.



A drawing of one of the largest specimens of the Fage form of *Lebetus* postlarvae, 8.1 mm long.

The interest in this discovery, paradoxically, is that it confirms what was discovered by two other workers almost half a century before. In 1919 the Danish marine biologist C. Petersen identified the postlarvae of a goby as *Lebetus scorpioides*, and a year before L. Fage had found postlarvae of the other known species, *L. orca*. Both species had been described from Scandinavian waters in 1874 by Collett. Later work by A. V. Tåning on *Lebetus* from Iceland and Faroes confirmed that the postlarvae of the two named species could be distinguished in several ways, notably in their length at development of certain features.

It was thus widely accepted that there were two species of *Lebetus* in European waters, an assumption which was demolished by P. Miller in 1961 (*Nature*, **192**, 675 ; 1961) who postulated that the two named species were sexually dimorphic forms of the same species. His hypothesis was exhaustively reinforced in a later paper (*Bull. Brit. Mus.* (*Nat. Hist.*), **10**, 205 ; 1963), in which he showed that, having examined more than eighty specimens of full grown *Lebetus*, including the types of both species, and dissected much of the material, he could find only male specimens of *L. orca*, and immature male and female *L. scorpioides*. This seemed to prove a classic case of sexual dimorphism in *Lebetus* (and other gobies are known to be sexually dimorphic), and Miller's conclusion has been generally accepted.

The work of Demir and Russell, however, has shown that *Lebetus* cannot be dismissed as a monotypic genus, for in addition to the morphological differences they have demonstrated biological differences. Collections made in 1970 of young fish in the western English Channel revealed forty-two "Petersen type postlarvae" and more than four hundred of the "Fage type", and it was established that the Fage type were more abundant between February and August, whereas the former were found from June to September only. The 1970 survey also showed that Petersen postlarvae were most common inshore; the other form was caught only at offshore stations.

It now seems therefore that there are two *Lebetus* species in the European Atlantic. If Miller's view of *L. orca* as a synonym of *L. scorpioides* (the only two named forms in the genus) is correct, then clearly one of the forms described from postlarvae by Demir and Russell is so far unrecognized and unnamed as an adult. On the other hand, it may be that both *L. orca* and *L. scorpioides* are good species, and if so it is to the credit of the earlier workers, Collett, Petersen and Fage, that their observations have been supported by this recent work on the postlarvae of *Lebetus*.

PLANT PATHOLOGY

Host-Parasite Contact

from a Correspondent

THE need for studies, on very short time scales, of the reactions arising from host-parasite contact was repeatedly stressed during a symposium on fungal pathogenicity and the plant's response, held at Long Ashton Research Station, University of Bristol, from September 22 to 24.

In his inaugural lecture, Professor R. K. S. Wood (Imperial College, London) emphasized the importance and specificity of the hypersensitive response (using the term in its botanical context). Originally applied to the death of cells in an incompatible relation between an obligate pathogen and a resistant host, it is now clear that the general concept may be more widely applicable. Of particular interest in this context was the demonstration by Drs A. Kaars Sijpesteijn and A. van Dijkman (TNO Biochemical Department, Utrecht) of the effect of two near-isogenic races of *Cladosporium fulvum* in causing leakage from cells of two tomato cultivars, which showed complementary host-parasite reactions. Other contributions were devoted to the nature of the trigger system which initiates the biochemical and structural reactions that occur when a plant is challenged by a potential pathogen. The complexity of compounds implicated in disease resistance makes it difficult to resolve the sequence of cause and effect.

The intensive studies during the past 30 years on the role of ethylene were reviewed by Dr E. C. Hislop (Long Ashton Research Station) who drew attention to the possible implications of ethylene in altering the rate of disease development, and Dr Barbara Lund (Food Research Institute, Norwich) demonstrated that bacterial enzymes probably activate the production of ethylene by a route already present in normal tissue.

By original definition, phytoalexins are absent in the unchallenged host plant but the symposium suggested no such clear-cut distinction between preformed and induced resistance factors.

Because obligate pathogens cannot be grown in axenic culture, it is particularly difficult to examine the pathogen component of the host-pathogen system. The use of tissue culture has been of some value but, as shown by Dr D. S. Ingram and Dr Inez Tommerup (University of Cambridge) with *Peronospora farinosa* on sugar beet callus tissue, it is not necessarily typical of the system *in vivo*. Electron microscopy has been increasingly used to study the structure of the host pathogen interfaces, where interchanges of nutrients, regulatory compounds, proteins, and perhaps even genetic material must occur. The participants were impressed by the elegance of such ultrastructural studies seen in the illustrations of Professor P. H. Williams (University of Wisconsin), Professor C. E. Bracker (Purdue University) and Dr L. J. Littlefield (North Dakota State University), Professor Williams showing how, in cabbage clubroot, the bullet-like "stachel" from encysted zoospores penetrate in a matter of seconds, but minutes are apparently required for the host to respond.

In his closing remarks, Professor P. W. Brian (University of Cambridge) considered that the present era of plant pathology has the same advancing frontiers as molecular biology and plant biochemistry. The study of host-pathogen interactions has not so far aided the chemical control of plant disease, but the symposium illustrated the delicacy of the balance of such interactions, better knowledge of which may lead to new ways of combating the pathogen.

Mutating the Rous Sarcoma Provirus

FURTHER evidence, if any were needed, that the replication of RNA tumour viruses involves a DNA replicative intermediate, the provirus, is reported by Bader and Brown in next Wednesday's *Nature New Biology*. These authors have exploited the reverse transcription of Rous sarcoma virus genomes to obtain mutants of this virus which are temperature sensitive for transformation. They argued that if chick cells are exposed to 5-bromodeoxyuridine, the mutagenic analogue of deoxythymidine, when they are infected with Rous sarcoma virus some BUdR should be incorporated into the DNA provirus as it is synthesized, presumably by the reverse transcriptase in the infecting virus particles. Furthermore, when the DNA proviruses containing BUdR residues in place of some of their thymidine residues are in turn transcribed to yield progeny RNA genomes, guanine for adenine base substitutions should be induced and some mutant progeny Rous genomes would be expected.

Bader and Brown found that if chick cells are simultaneously infected with Rous sarcoma virus and exposed to BUdR, but not if the exposure to BUdR is 12 hours before or 12 hours after infection, temperature sensitive progeny virus can indeed be isolated from the transformed cells some 24 hours after infection. Such progeny virus stocks transform chick cells more efficiently at 36° C than 40.5° C, whereas the converse is true of wild type Rous sarcoma virus. This observation immediately suggested that many of the progeny virus particles liberated from the cells exposed to BUdR contain temperature sensitive lesions in the gene or genes responsible for transformation.

To prove this point, Bader and Brown isolated the progeny virus produced by 119 clones of cells transformed in the presence of BUdR and found that of these 20 yielded mutant virus temperature sensitive for transformation. Because BUdR is not metabolized into RNA by chick cells this result must mean at the very least that that part of the Rous sarcoma genome which determines the ability to cause the transformation of chick fibroblasts must be replicated by way of a DNA intermediate. Moreover, because cells transformed by these mutants at their permissive temperature and then shifted to the nonpermissive temperature continue to produce progeny virus, the temperature sensitive lesion cannot be interfering with the replication and packaging of the mutant genomes.

LIPIDS

Protomembranes

from our Molecular Biology Correspondent

IT seems that the study of hydrocarbons will for some time continue to provide a comfortable livelihood for many a physical chemist in the guise of a molecular biologist. The possibilities in liposomes are still far from exhausted, and McConnell especially has shown how much structural and dynamic information can be extracted from his spin-label experiments on such systems.

Cadenhead and Katti (*Biochim. Biophys. Acta,* **241**, 709; 1971) have tried to step on the cake by showing that a molecule carrying a large and ugly spin-label group will not necessarily have the same physical properties as the virgin form. There is no complete counter to this criticism, though it can be argued that inasmuch as spin-labelled lipids can be biosynthetically incorporated in membranes, they seem to be at least compatible, if not identical in behaviour, with normal lipids. Moreover the results of other methods, including NMR and X-ray diffraction, seem to be converging on much the same conclusions. Cadenhead and Katti, however, have looked into the effects of oxyloxazolidine-substituted cholesterol-like steroids on the surface properties of films, in which they are mixed with myristic acid. The polar spin-label group, they find, changes the effect on the surface isotherms considerably, compared with the parent compound; they suggest that this will generally be the case and recommend caution in visiting the results of spin-labelled onto unlabelled systems.

At the same time Birdsall *et al.* (*ibid.*, 693) offer support for the conclusions of Hubbell and McConnell concerning configurational freedom of lipid chains in bilayers. Instead of introducing the relatively large and polar spin-label, they have prepared a series of stearic acids containing a fluorine atom at various positions in the paraffin chain. These derivatives were then mixed with lecithin and dispersed in water as vesicles. NMR signals from the ^{19}F nucleus revealed that the line-widths changed drastically with the distance of the fluorine from the head group, indicating a large increase in freedom of motion going from the outside to the centre of the bilayer. This is by now a heavily laboured conclusion. It may be hoped, however, that a more complete analysis, including an estimate of exchange line-broadening effects, will make possible a quantitative treatment, so as to allow quantitative comparison with the results of other methods.

The most interesting current development in the application of NMR to the study of such systems comes from the Moscow group (Bystrov *et al., Chem. Phys. Lipids,* **6**, 345; 1971), who have examined the effect of paramagnetic perturbants on the proton magnetic resonance spectra of lecithin vesicles. When vesicles are prepared in water (or actually D_2O) containing manganous ions, there is a spectacular broadening effect, primarily of the signal from the quaternary amine methyl hydrogens, because these are in contact with the aqueous medium on the inside and outside of the vesicle. The ions do not penetrate the bilayer, however, so that when the vesicles are made in water and the paramagnetic ions are only afterwards added, a quite different effect is observed: superimposed on the shallow broadened background is a sharp peak of diminished magnitude. The polar heads on the inner surface are not in contact with the ions, and thus give rise to the sharp unperturbed resonance, whereas those on the outer surface generate only the broadened pedestal. When such preparations are sonicated, the residual sharp line from the internal head groups vanishes into the broadened background. An equally spectacular effect is observed with europium ions, which elicit a large contact-shift in the head-group resonance, so that when they are added to preformed vesicles, two sharp signals, one from the internal, the other from the external head groups, are observed.

Bystrov *et al.* also prepared micelles of lecithin in benzene, and found that these could be made to take up water. Again the introduction of the paramagnetic perturbent perturbed only the head groups exposed to water on the inner surface. These experiments offer good promise for the separate observation of events at different surfaces both of models and of real cell membranes.

A review by Kuhn and Möbius (*Angew. Chem.*, **10**, 620; 1971) of their remarkable work on monolayer systems, and the use of excitation transfer to measure critical distances, will give workers in the biological membrane field much food for rumination. The scope of this work takes in many areas of chemistry, but some examples of biological interest have been included in the survey, in particular the measurement of membrane thickness by introducing the membrane between emitter and sensitive layers and measuring the efficiency of excitation transfer and the construction to order of various arrangements of lipid and protein monolayers.

Rescuing Mouse Sarcoma Virus

IN next Wednesday's *Nature New Biology,* Klement, Nicolson and Huebner report that they have rescued mouse sarcoma virus particles from rat cells which although transformed by this virus do not support its replication until they are exposed to appropriate concentrations of 5-bromodeoxyuridine (BUdR).

This discovery, which follows hard on the heels of those of Rowe's group (*Science,* **174**, 155; 1971) and Aaronson, Todaro and Scolnick (*ibid.*, 157), who have used BUdR and IUdR to rescue respectively mouse leukaemia virus from non-producing AKR strain mouse embryo cells and a C-type virus, of which the oncogenic potential has yet to be tested, from normal BALB/C 3T3 fibroblasts, is a powerful shot in the arm for the devotees of the oncogene hypothesis of malignant transformation. And of course the induction with BUdR of IUdR technique provides a new approach to the search for other mammalian, including human, RNA tumour viruses.

The experiments of the three groups, which are essentially identical, indicate that the drugs BUdR and IUdR, for reasons that are far from clear at present, stimulate the active replication of dormant RNA tumour virus genomes in rat and mouse cells. The virus which Rowe's group have activated in embryonic cells of the AKR strain, a high leukaemia strain, seems to be identical to that isolatable from adult AKR mice with the disease. The virus which Todaro's group have activated in 3T3 cells has all the vital statistics of a C-type RNA tumour virus and it will be fascinating to learn whether or not it is indeed oncogenic. And Huebner's group believe that the rescue of mouse sarcoma virus from transformed but non-producing rat cells is most probably a consequence of the activation of a dormant rat "leukaemia" virus which can provide the helper function required for the replication of mouse sarcoma virus and normally provided by mouse leukaemia virus.

The avian oncogenic virologists, and Weiss in particular, have, of course, already shown that a C-type virus, probably an avian leukosis virus, can be activated in the cells of domestic chicks and wild jungle fowl by various chemicals including carcinogens, and so the betting must be that all vertebrate cells have the genetic potential to specify C-type viruses at least some of which are oncogenic. And that is what Huebner and Todaro's oncogene hypothesis predicts; perhaps all cells do indeed carry genes which can render them malignant.

ESTUARIES

Inaugural Meeting

from a Correspondent

THE inaugural meeting of the Estuarine and Brackish Water Biological Association was held at the Zoological Society of London on October 13. After the formal founding of the association by Dr D. S. Ranwell (NERC Coastal Ecology Research Station), it was announced that the steering committee would act as the first council and that the constitution would be approved at the first annual general meeting in April 1972. Some participants suggested that the word "biological" should be deleted from the name of the association, because the association plans to encourage an interdisciplinary approach to studies of estuaries. Mr R. Bassindale (University of Bristol) serves as the first president and Dr R. S. K. Barnes (Central Electricity Research Laboratories, Fawley, Southampton) is the secretary, from whom full details of membership may be obtained.

A symposium on the estuarine environment was held during the remainder of the meeting. The symposium was opened by Professor W. D. P. Stewart (University of Dundee), who reviewed the sites of estuaries in the United Kingdom and estuarine research projects which are in progress. Professor Stewart stressed the importance of estuaries in relation to man's activities and the need to develop management policies and a strategy for research.

Professor L. C. Beadle (University of Newcastle upon Tyne) discussed physiological adjustments shown by organisms in relation to extreme fluctuations of ionic conditions which may occur in estuaries. He stressed the need for information on the time which organisms take to adjust to salinity stress, how this affects growth rates and the extent to which changes in ionic fluxes may be used as indicators of salinity stress before more adverse effects of stress on organisms are apparent.

Mr A. J. Phillips (Central Electricity Research Laboratories, Fawley) stressed that although there is a considerable body of scattered information on the chemistry of estuaries, there is a lack of guiding principles. He also emphasized the differences in the chemistry of sea water and river water, not only in relation to ionic activities but also in relation to different ionic species present in the two types of solution. He suggested that the amounts of trace elements present in sea water and estuarine water may be underestimated by the use of some methods, because a fraction of these elements is bound to particulate matter carried in suspension. The particulate matter tends to flocculate in the presence of high salinities.

The last speaker in the morning, Dr K. R. Dyer (University of Southampton), spoke on sedimentation in estuaries. Salinity levels are extremely important, besides topography, current flow and volume of water, in determining rates of sedimentation. Various degrees of mixing may occur between river and sea waters, resulting in the formation of completely stratified to completely mixed bodies of water. The principal minerals in sediments are illite, montmorillonite and kaolinite which have different fall velocities that in part are dependent on temperature and salinity. A mean sedimentation rate for estuaries in Britain is approximately 0.2 cm per annum. Under some conditions, fluid muds are present close to the bottom of estuaries which during ebb and flow tides may give rise to peaks in turbidity.

In the afternoon, Dr R. L. Jefferies (University of East Anglia) reviewed the research on salt marshes. He emphasized the high net productivity of marshes and suggested that plants growing under high salinities are often perennial, show vegetative reproduction and have a limited but rapid growth period. He also discussed the possibility of assaying adaptive enzymes such as nitrate reductase in plants in an attempt to measure the level of nitrate-nitrogen available for plant growth in enriched estuaries.

Dr P. R. Walne (Ministry of Agriculture Shellfish Laboratories) spoke on the importance of estuaries to commercial fisheries. He concentrated on the shellfish industry which has an annual turnover of £0.5 million in Britain and examined methods for improving yield such as the moving of shellfish or encouraging sprat to settle.

Dr H. Milne (University of Aberdeen) examined the trophic relations at the upper end of the food chain in an unpolluted estuary, the Ythan in Aberdeenshire. Although the results are preliminary, he has been able to determine the annual energy budget of mussel populations in commercial beds and to show that predation by birds together with loss of energy as a result of metabolism during the winter cause the principal reductions of energy in the standing crop.

Mr M. J. Barrett (Water Pollution Research Laboratory, Stevenage) discussed changes in the oxygen levels in the waters of the Thames during a period of 80 years and how in the past 15 years conditions have improved so that anaerobic reaches are no longer present.

In the closing contribution, Professor D. R. Arthur (King's College, London) emphasized the need for interdisciplinary studies on estuaries and stressed the approach used by systems analysts in gaining a better understanding of estuarine systems.

Dilatons and Gravity

IN the continuing attempt to establish connexions between the microscopic and macroscopic worlds of physics, it is becoming fashionable to explore gravitation from the standpoint of elementary particle physics; and in next Monday's *Nature Physical Science*, Y. Fujii of the University of Tokyo describes a contribution to this approach. The starting point of his work is the prediction of the Goldstone theorem that the invariance of the world under scale transformations (dilatations) can be realized physically by the existence of a massless boson, known here as the "dilaton". Any breaking of scale invariance results in a non-zero mass κ for the dilaton, with a consequent finite range κ^{-1} for any physical effects. If the dilaton is now coupled to gravity, it would manifest itself by a modification of the usual Newtonian force law in the range κ^{-1}. The choice of κ is entirely arbitrary, but a characteristic mass may be constructed from gravitational and elementary particle parameters, and this leads to values of κ^{-1} of a few km or less.

Fujii's concern is to devise experiments to detect any such short range non-Newtonian component, if it exists. Several suggestions are made for laboratory and larger scale searches for this component. The chief difficulty with all these experiments is to achieve sufficient sensitivity. The most direct method—the Cavendish experiment in its refined form—could almost detect a component with $\kappa^{-1} \sim 10$ m. An amusing terrestrial experiment is also suggested in which the change in gravity due to the lowering of the water level in a large semicircular reservoir is measured. Other terrestrial approaches would be to compare the size of the Earth as measured by astrogeodetic techniques with the radius calculated from the gravitational force at the Earth's surface. Or the variation of gravity with altitude could be explored. Although astrophysical considerations might be expected to be the most appropriate for testing gravitational theories, only one extra-terrestrial experiment is mentioned, that of observing the behaviour of artificial lunar satellites which orbit close to the surface of the Moon and would be perturbed by a short range force.

Unfortunately, in all these large scale experiments it is impossible to make correct allowances for the many other complicated effects, such as those due to inhomogeneities beneath the terrestrial and lunar surfaces. Nevertheless, Fujii places present limits on κ^{-1} of either between 10 m and 1 km, or less than 1 cm.

PEAT

Pennsylvanian Deposits

from a Correspondent

WETLAND ecosystems are particularly prone to human interference. Either they are drained for agriculture or they are exploited for peat, but rarely are they left untouched. The reason for this is probably that it is difficult to justify mire conservation except in terms of the intrinsic scientific interest of the habitat, which appeals only to a relatively small minority of the population. The interest of these habitats lies both in their distinctive wildlife and also in that they build up a record of their own development in the peat which they form. Peat is an accumulation of the remains of dead vegetation which once grew upon the surface of the mire. Waterlogged, anaerobic conditions discourage microbial activity so that decay processes become impaired. Such remains are often recognizable and document the vegetational succession on the site. Furthermore, the peat contains pollen which may have travelled considerable distances in the air before being deposited on the mire surface and from this can be reconstructed the vegetational history of much larger areas surrounding the mire. Such information can be valuable in the study of climatic changes in a region.

Peat has long been valued as an energy reserve, a fossil fuel of recent origin. But in recent times its value as a horticultural commodity has risen very considerably, a value which derives from certain of its physical properties. In the first place it is a source of organic matter which, when added to a well aerated soil, acts as an energy source for soil microbes and thus improves soil structure. The water holding capacity of peat is very high, its value depending upon the vegetation from which it was formed, for example, *Sphagnum* moss peat can hold 800 per cent of its dry weight in water, and for sedge peat the figure is about 400 per cent. Peat also has properties of nutrient retention which make it valuable when added with fertilizers to soil. This horticultural demand for peat has placed a new stress on the world's harassed wetlands.

A recent bulletin of the United States Geological Survey (C. C. Cameron, Bulletin 1317–A; 1970) is devoted to the peat deposits of the Appalachian Mountain region of north-east Pennsylvania. The author calculates that the resources of this 900 square mile area are more than 13 million short tons of air dried peat. This estimate is based on a study of ninety-five peat deposits most of which are less than 100 acres in area and less than 16 feet deep. In spite of the small size of these resources (between 10,000 and 100,000 tons each), the proximity of the Atlantic seaboard and metropolitan markets for peat products makes their exploitation an economic possibility. In 1966 the United States imported peat to the value of $11½ million. With a demand of this size it is understandable that the Department of the Interior should seek a home supply of peat. If economic needs demand the exploitation of an area such as north-east Pennsylvania, this should be accompanied by the conservation of selected sites representative of the wide range of mire types found in that area. In this way the irretrievable loss of valuable ecological information can be avoided.

PLANT GROWTH

Izmir Institute

from a Correspondent

"NEVER has so much been said by so many on a subject about which we know so little." This remark, which was made at the 1955 Wye College conference on plant growth regulation, is perhaps as true today as it was then. The NATO Advanced Summer Institute on the same subject, which was held at Izmir in Turkey from September 20 to October 1, highlighted the complexity of the interactions between the classical auxins and the gibberellins, cytokinins, abscisic acid and ethylene. It also stressed the need for "translating" results obtained on segments of plants to whole plants.

The organizers arranged for a general review to precede the more detailed accounts of research on specific topics. This met one of the objectives of the NATO institute; that is, to provide students with a general survey of the field while at the same time providing a forum for research workers to present original work. Dr I. D. J. Phillips (University of Exeter) opened the proceedings with a review of the principles of promotion and inhibition of growth in plants. This was followed by an original paper by Professor E. C. Cocking (University of Nottingham) on specific discussion of growth in isolated protoplasts. Other contributions from the United Kingdom included reviews on the gibberellins (Dr J. Macmillan, University of Bristol), some recent studies on gibberellin-like substances in higher plants (Dr J. L. Stoddart, Welsh Plant Breeding Station) and growth regula-

How the Molecules of Collagen are Assembled

NEXT Wednesday's *Nature New Biology* will see the publication of the third article in the past few months on a longstanding problem in molecular biology; how the molecules of collagen are assembled in three dimensions to produce functional connective tissue. Each approach starts with different data and it is interesting that they all point to the same solution—a five-fold microfibril.

The latest study comes straight to the point that any answer must finally explain. How is the molecular packing related to the molecular structure? Segrest and Cunningham start with the tropocollagen molecule, a three-strand rope formed by supercoiling two identical helices termed α_1 and α_2. They speculate that the primordial collagen may have contained three identical chains of general structure (gly-pro-X)- where X is apolar. Fibril formation would likely take place by more or less random parallel aggregation of such molecules. They then suppose that a mutation in the nucleic acid led to a charged side-chain at the same level in all three α chains, followed by a second mutation which resulted in the appearance of a second charge side-chain, complementary to the first and separated by a suitable distance along the molecule. If the relative positions of the two new complementary groups are correct, fibril growth may proceed by lateral accretion of staggered molecules.

In addition to appropriate position along the length of the molecule, several factors are involved in the correct relationship of mutations for fibril growth. When parallel cylinders are packed they touch along edges of contact. For helices, points which lie along such an edge must be separated axially by integrals of the pitch of the helices. Thus mutations can only occur along these edges for formation of a regular fibril. Segrest and Cunningham list the types of packing which could result from various mutation positions. One of these is a hexagonal array; another is an extended pleated sheet. The third is the five-fold microfibril suggested independently on other grounds. The two identical α_1 chains in the tropocollagen molecule are related by an aximuthal rotation of 108°, so that the existence of contact edge on one chain automatically generates an identical edge 108° round from the first. If complementarity of these edges can be obtained by an axial stagger, then a second molecule would add to the first at an angle of 108° which is the internal angle of a pentagon.

Model building has its limitations. Without further information it is frequently only able to indicate possible structures. It is gratifying to see how the microfibril suggested by X-ray diffraction and electron microscopy arises readily from the structure of the component molecules.

tion in a whole plant (Professor A. J. Vlitos, Tate and Lyle, Ltd, Keston), and some aspects of growth control in cereal seedlings (Dr L. L. Mer, Imperial College, London).

The transport of auxins, gibberellins and cytokinins was discussed by several participants. Professor W. P. Jacobs (Princeton University) presented evidence for the polar transport (in *Coleus*) of all of the three classes of growth regulators. Professor T. K. Scott (University of North Carolina) demonstrated that the movement of gibberellins in sugarcane tissues is strongly influenced by auxins and perhaps also by other endogenous growth regulators. Dr H. Kaldewey (University of Saarlandes) presented good evidence for polar movement of radioactive ^{14}IAA in the stems and in the roots of intact cotton seedlings. An original concept for explaining apical dominance was presented by Professor Y. Vardar (Ege University, Turkey). Professor H. Bürstrom (University of Lund) demonstrated quite conclusively that the anatomy (that is, cell type) of a given tissue determines to a considerable extent the velocity of movement of growth regulators through the tissue. He also demonstrated the histological effects on cells after treatment with various classes of growth regulators.

Interactions between the various classes of endogenous growth regulators were reviewed by Professor A. W. Galston (Yale University) and by Professor A. C. Leopold (Purdue University). Both speakers stressed that auxins, gibberellins, cytokinins, abscisic acid and ethylene operate in a dynamic system where the presence of one type of growth regulator influences the physiological activity of another. Auxin, for example, may predispose a cell to respond to a gibberellin, and in some instances treating a tissue with a gibberellin induces it to produce more auxin; in turn this may lead to a release of ethylene. Ethylene may produce a host of physiological responses including the induction of flowering in tissue cultures of higher plants as was demonstrated by Dr C. Nitsch (CNRS, Gif-sur-Yvette).

Dr O. M. Heide (Makerere University) reviewed some of the physiological effects of cytokinins with special reference to the induction of rooting and initiation of buds. He demonstrated that these effects were mediated by temperature. Of particular interest was the demonstration that rooting of cuttings can be stimulated by cytokinins under certain conditions.

The role of ethylene in plant growth was discussed in some detail by Dr S. P. Burg (University of Miami). As one delegate remarked, "Ethylene can do anything an auxin can do and even better". Dr Burg demonstrated that ethylene is indeed a very active plant growth regulator but an extremely difficult and elusive compound to study, chiefly because it is a gas.

A thorough review of the auxins and other auxin-like substances by Professor K. V. Thimann (University of California, Santa Cruz), followed by a more specific contribution by Dr J. Shen-Miller (Argonne National Laboratory), set the stage for lively discussions on whether the classical auxins, as studied in isolated plant parts and in dark rooms, are as relevant to the growth of intact plants as was once thought. Dr Mer indicated, in discussion, that some of the published results may be interpreted in more than one way and that extrapolations to whole plant physiology from such results are invalid.

Inhibitors of growth, some new synthetic growth regulators and some interesting and aberrant physiological effects of auxins on growth were also discussed. Dr K. Dörffling (State Institute for General Botany and Botanic Garden, Hamburg) reviewed the status of abscisic acid as a naturally-occurring plant growth regulator.

A thorough description of the synthetic growth regulators, known as morphactins, was presented by Dr G. Schneider (E. Merck AG, Darmstadt). These substances retard the growth and development of dicotyledonous species and in the future may have important practical applications.

Professor L. Lona (University of Parma) presented evidence that indole-3-butyric acid (IBA) acts as a gibberellin-like substance in certain species. He stressed the need for evaluating the physiological effects of any given growth regulator on a wide range of species before attempting to classify the regulator.

Heterogeneous Nucleation from a Polymer Melt

THE ingenious researches of David Turnbull in the nineteen-fifties stimulated a great deal of work on the mechanisms and temperature dependence of nucleation in supercooled metallic and molecular melts. The classical Becker–Volmer theory of homogeneous nucleation is now firmly established for these categories of materials, but at the same time it has become clear that nuclei form homogeneously only under very exceptional circumstances: normal melts contain specks of impurity that act as nucleation catalysts. *A fortiori*, crystals forming from polymer melts would be expected to be heterogeneously nucleated always, in view of the extreme improbability that a sufficient length of polymer chain should align spontaneously in the correct configuration to constrain further growth in the proper pattern. But so far no heterogeneous nucleation catalyst for a polymer has been properly characterized and, generally speaking, this aspect of polymer science is confused.

In next Monday's *Nature Physical Science*, S. Y. Hobbs casts some light on this problem. Hobbs crystallized spherulites of isotactic polypropylene from the melt, using short lengths of carbon fibre as nucleation catalysts. These were standard 'Morganite' fibres made from a polyacrylonitrile precursor, and two fibre variants were used —high strength (type 1) and high modulus (type 2). Type 1 fibre is known, from electron microscopy and small-angle X-ray scattering, to consist of very small turbostratic graphite crystallites of random orientation, whereas type 2 contains larger, highly oriented crystallites, with the basal graphite planes parallel to the fibre axis. Hobbs found that type 2 fibres were highly efficient nucleation catalysts, whereas type 1 fibres were ineffective.

The polymer chains in the crystalline structure of polypropylene are arranged in straight spirals. Hobbs showed that such a spiral can be accurately keyed to a graphite basal plane through some of the hydrogen atoms which (according to recent molecular orbital calculations) are preferentially chemisorbed at the midpoints of C–C bonds in the graphite structure. For effective nucleation the spiral has to be "set", perhaps along one complete repeat period, and this requires the graphite basal plane which serves as substrate to exceed a certain minimum dimension, which Hobbs estimates at 50 Å. In type 2 carbon fibres, the constituent crystallites are more than 100 Å across measured in the basal plane, whereas in type 1 they are only ~25 Å across. The inefficacy of type 2 fibres is thus readily understood.

Type 2 carbon fibres have a crystallographic "fibre texture", which implies that the normals to the basal plane are randomly distributed in a plane normal to the fibre axis. It would be interesting to continue Hobbs's work with single crystals of graphite or alternatively with highly oriented pyrolytic graphite. On the basis of Hobbs's interpretation of his observations, polypropylene would be expected to crystallize on such a substrate in two-dimensional spherulites, all polymer spirals being constrained to lie parallel to the exposed graphite basal plane. This form of nucleation would generate a unique form of preferred orientation with, presumably, strongly anisotropic properties.

Outlook for Controlled Fusion Power

J. L. TUCK
University of California, Los Alamos Scientific Laboratory, Los Alamos, New Mexico

Fission and fusion are compared as a source of energy for the future. Energy reserves for the two are similar, as are their pollution and ecological characteristics. A remote integrated site policy is recommended for fission.

UNTIL now mankind's chief energy source has been fossil fuel. Within the next century, if the population continues its present growth, rising energy demands and falling fuel reserves will force us to find new sources of energy and, although several possibilities exist[1-4], it looks at present as if the chief energy source of the future is likely to be either nuclear fission or nuclear fusion.

Comparison of Fission and Fusion

The advantages of nuclear fission as an energy source are, first, that the fuel reserves are large. The fuel used in fission reactors at present is obtained from rich ores, at a cost of ~\$5.00 per pound of UO_2, for which the reserve is small—a hundred years at most. But for weak ores (containing ~10 p.p.m. of UO_2), which would be uneconomic to extract at the present time, the reserve is large. Thus, using the customary energy unit $Q(=10^{18}$ BTU $=10^{21}$ J), the reserve at the 10 p.p.m. level will be about 10^6 Q if the uranium is used efficiently in breeder fission reactors. The present annual energy consumption rate of the world is 0.2Q, and it has been estimated[3] that for a world with an asymptotic population of 7×10^9 this might rise to 2 to 3Q a year. This asymptotic world has then about one million years supply of energy in its reserve of accessible fuel for fission.

The second advantage of fission is that non-breeder fission reactors are available and already producing power competitively. Breeder fission reactors exist only as prototypes at present but are in a state of intense development. They are expected to come into wide commercial use in the next decade and to be competitive power sources. The third advantage is that fission reactors pollute less than coal burning power plants.

The disadvantages of fission as an energy source are, first, that the plants are hazardous (because of possible melt down, power excursions and so on). But a major bomb-type explosion is probably impossible and precautions, involving heavy containment vessels and fail-safe cooling equipment, are taken to prevent escape of radioactive material into the atmosphere as a result of imaginable accidents. But no matter how safe they are made, they can probably never be made entirely safe from technically informed sabotage. It seems unlikely, therefore, that they will ever be installed within cities.

The second disadvantage is that the plutonium by-product is a material fundamental to nuclear weapons. In an asymptotic world running on fission, there would be enough to make tens of thousands of nuclear bombs a year. It follows then, that the rise to power of, say, a Hitler would assure a Götterdämmerung finale. Third, the plutonium is valuable, saleable, and therefore likely to be stolen. Mankind's past behaviour suggests that, sooner or later, somebody will "cobble" a crude fission bomb—of a kiloton or so—and fire it in a city centre. Fourth, fission products are biologically hazardous and probably should not be transported over long distances for fear of dispersion by accident.

The first fusion plants will have to operate on the, thermonuclearly speaking, less difficult, deuterium–tritium (DT) cycle. The factor determining fuel reserves will not be deuterium but lithium and the reserves of this are about 2×10^6Q or enough to last about 10^6 yr; ultimately fusion plants operating on the DD cycle and fuelled by deuterium may be achieved. Deuterium is present to the extent of 1 part in 50,000 by weight of the oceans of the Earth and constitutes an energy reserve of 10^9Q—a fuel reserve for about 10^9 yr at the asymptotic Q rate. Second, fusion reactors are incapable of running out of control and it follows that they could, if necessary, be located inside urban complexes. They also generate no fission products and, although the tritium is valuable and subject to theft, it is not adaptable to the construction of illicit bombs.

The disadvantages of fusion are, first, that fusion power is not yet available; second, that it seems as if fusion reactors will be more complicated than the basically very simple fission reactor, though this may not necessarily always be the case and it is too early to be sure. This suggests, however, that it will take time for fusion power to become competitive with fission. Third, although a fusion power reactor produces no long term radioactive fission products, it will produce about ten times as many neutrons kWh^{-1} as a fission reactor. This means that a high level of neutron activation will take place in some components of the reactor and precautions in plant design and hygiene will have to be taken to prevent the creation and escape of biologically hazardous nuclei. Fourth, tritium will be present and will be processed in large quantities in a fusion reactor. Although tritium is a biological hazard, it is less dangerous than most radioactive species because of its rapid dissipation in the atmosphere and because of the low penetrating power of its radiation.

Fifth, a fusion reactor operating on the DT cycle will contain large quantities of fused lithium in the form of a layer of thickness 1 m around the reaction space. Lithium is a chemical fire hazard in the same way as the sodium in fission reactors.

Even a technically expert saboteur in a fusion power plant could do no more than stop it and, in the case of a DT cycle plant, set off a lithium fire and release tritium in quantities that would not be catastrophic but would depend on the construction of the plant.

Fission, with all its disadvantages, could be improved by a wise siting policy. This would be to install plants on remote sites with their own fuel element processing and fission product disposal (and preferably, for its thermodynamic advantage, with cold water cooling). Fuels would enter such a plant but no radioactive or fissionable material would leave it. This reduces the hazard of fissionable material dispersal by theft and is also advantageous because of the low density of the surrounding population. Such plants would naturally form the power input points of a nationwide power grid. Many advanced countries today have such grids and, although a linking of privately owned power companies is taking place in the United States, the formation of a national power grid is somewhat overdue.

The objections made to such an obviously logical course by power plant operators have been, first, the high losses in long distance bulk power transmission, and, second, the high right-of-way costs of bringing transmission lines into cities. Both these arguments are valid if only on account of many years of neglect of development in the field of power generation and transmission. Overhead high voltage d.c. transmission as developed in Sweden is being tried in the United States (Bonneville to Los Angeles). The transmission of high voltages underground, ultimately by superconducting lines, is obviously the way to bring power into cities, both from the point of view of the amenities and the cost of right-of-way.

According to a recent *Fission Power Reactor Review*[12], there are more than 300 large fission reactors in existence or being built. Thus, fission power not only exists but is in a flourishing state. The disadvantages fission has will have to be lived with and it is not too late to do better. Fusion does have advantages over fission, and, in my opinion, will ultimately supersede it. The critical question is—when might this takeover occur ?

Time Scales

December 1942 is the birth date of fission, when the first pile went critical. Two years later, under the wartime thrust of the Manhattan project there came into existence a 1,000 MW (thermal) fission reactor (Hanford). It is less easy to put a firm date on the achievement of economic fission power—1965 might be correct for the United States, but it came earlier in Britain where power costs are higher and competitiveness easier to achieve. Accordingly, the development time of fission power from birth to usage will be taken as twenty years.

The term feasibility has been widely used in the search for a comparable birth date for fusion. The energy balance for a fusion reactor plasma is determined first by the ion temperature T_i which must be above a certain minimum value—$\sim$10 keV for most reactor geometries using the DT cycle but as high as 100 keV for the special case of the mirror machine with direct conversion. The second determining factor is the Lawson energy balance criterion $n\tau$, where n is the plasma density and τ the plasma confinement time. These two parameters can evidently be traded off against one another and so there can be a considerable range of parameters capable of satisfying the $n\tau$ reactor criterion, that is low density and quasi-steady state (with $n \sim 10^{15}$ ions cm^{-3}, $\tau \sim 1$ s) up to high density, pulsed state (with $n \sim 10^{23}$ ion cm^{-3} and $\tau \sim 10^{-8}$ s). The energy break-even point for a DT reaction is at $n\tau \sim 10^{14}$ ion cm^{-3} s, and the achievement of this has been called feasibility. For a reactor, one would need to achieve $n\tau \sim 10^{15}$ say, which would give an output of about ten times the input.

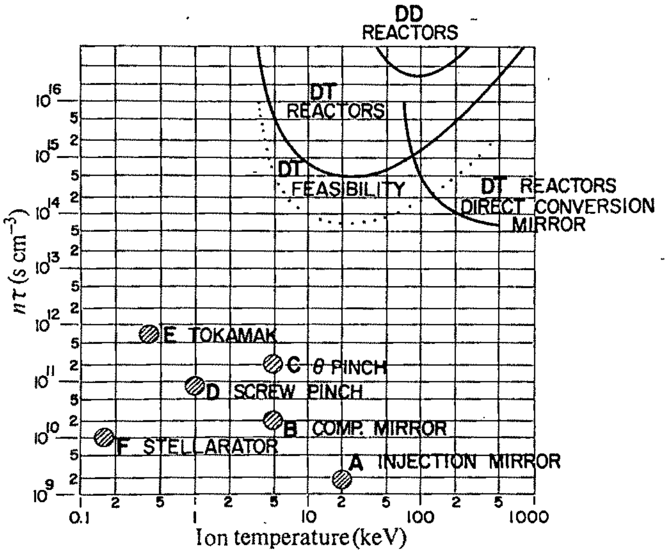


Fig. 1 Status diagram of fusion approaches to power reactors. *A*, Injection mirror machine Phoenix (Culham, UK); *B*, compression mirror machine 2*X* (Livermore, USA); *C*, θ-pinch Scylla 4 (Los Alamos, USA), also ISAR I (Garching, W. Germany); *D*, screw pinch ISAR IV (Garching, W. Germany); *E*, Tokamak T-3 (Moscow, USSR) since duplicated by S.T. (Princeton, USA); *F*, Stellarator-C (Princeton, USA).

In Fig. 1, these quantities T_i and $n\tau$ are plotted on an achievement chart for the plasmas at present obtained in reactor-oriented experiments. (The laser-heated DT pellet approach (for example) is, however, too recent for significant plasma achievements to have been made.) Although at this early stage it is probably not significant, the θ-pinch is at present leading the race to reach feasibility by a factor of 2 in T_i and 100 in $n\tau$. But an increase in $n\tau$ by a factor of 10^3 is still necessary before reactor status can be achieved. For the special case of mirror machines with direct conversion, the reactor target area is different, with a much higher T_i, >100 keV, but a lower $n\tau$, $\sim 10^{14}$.

For the benefit of those unaware that a controlled thermonuclear reaction had been achieved at all in the laboratory, it should be noted that the Scylla 4 θ-pinch plasma can generate (DT) a gross output of 100 kW of thermonuclear heat for a few μs. It is much too early to predict which of the contenders will reach the target first—the next steps forward at Tokamak (T–10) and at the θ-pinch (Scyllac) will, hopefully, advance $n\tau$ by a factor of 50.

The rate of achievement will depend in some less than linear way on the degree of financial support: a reasonable extrapolation at the current rate of progress suggests that feasibility might be reached by several routes in, say, 1980. Such an achievement would in no sense be a reactor; it would merely be a plasma which put out as much potentially recoverable energy as had been put into it—the engineering complexities, walls, heat exchangers would still lie ahead.

Starting from 1980 as the birth date for fusion, we now have to estimate the development time. It is hard to imagine anything simpler than a fission chain reacting pile, but a fusion reactor is bound to be much more complicated. It took twenty years to develop fission, but then there was no previous experience with radioactivity on a large scale.

I shall take the two factors of increased fusion complexity and increased engineering experience with radioactivity as mutually compensating, and the development period for fusion to be the same as for fission—twenty years. Competitive fusion can, therefore, be expected by the year 2000.

Fusion could have undoubted advantages over fission socially but from the point of view of ecology and pollution there is actually very little to choose between them, and both are greatly superior to fossil plants (especially those fired by coal).

Perhaps because of a confusion between the social and the ecological roles, fission has come under widespread attack from ecologists and anti-pollutionists recently, whereas fusion is being held up as the ideal. This use of fusion as a stick with which to beat fission seems also to have created a political polarization which is ill-founded technically and, if allowed to continue, may work to the disadvantage of fission, fusion and mankind generally.

For a fusion reactor to produce power, it must achieve the requisite ion temperature ($\sim$10 keV for DT, $\sim$50 keV for DD) for a sufficient $n\tau$ for the energy output from the thermonuclear reaction ($\propto \varepsilon n^2 \tau\, Q \overline{\sigma v}$ cm^{-3}) to exceed the input energy investment in heating the plasma ($\propto nT$ cm^{-3}); Q is the energy yield of the nuclear reaction, $\overline{\sigma v}$ is the nuclear reaction cross section averaged over the Maxwell distribution of velocities in the plasma and ε is the Carnot efficiency of the heat-electricity conversion. The aim of the magnetic confining system (bottle), if there is one, is to be as economical as possible both in its construction and energy running costs. This implies that the magnetic field B shall confine the maximum possible plasma pressure, or that the ratio of plasma pressure nkT to magnetic field pressure $B^2/8\pi$ shall be as near to unity as possible. A plasma confined by an external magnetic field has the fraction $(1-\beta)^{1/2}$ of that field inside. Some characteristic le I · Characteristic Parameter Values for a Possible DT Reactor Plasma

n temperature	T_i	10 keV ($\equiv 114 \times 10^6$ K)
lectron temperature	T_e	10 keV
on density	n	10^{15} ion cm^{-3}
lectron density	n	10^{15} electron cm^{-3}
Confinement time	τ	1 s
Plasma pressure	$2\,n\varepsilon T$	3.2×10^7 dyne cm^{-2} ($\simeq 32$ atm.)
Magnetic field	$\beta = 1$	21 kgauss
	$\beta = 0.01$	210 kgauss
Velocity of a 10 keV deuterium ion		10^8 cm s^{-1}

parameter values for a possible DT reactor plasma are given in Table 1.

The last parameter is an indicator of the rapidity with which the plasma moves when free to do so or with which it escapes when an instability defeats the magnetic confinement.

Tokamak

Tokamak is a large toroidal system with thick copper walls, and a toroidal winding encircling a magnetic core. A large current is induced in the plasma encircling the core, which heats the plasma resistively, and a large longitudinal magnetic field from the toroidal winding stabilizes the z pinch-like configuration; additional stabilization is provided by the conducting wall. The approach was devised early in the days of controlled thermonuclear research at the Kurchatov Institute, Moscow, by Artsimovich and his co-workers. From the 1950s onwards, a series of models of increasing size were produced but they aroused little interest among the main stream of plasma physicists. The breakthrough occurred in 1969 when an ion temperature of 0.4 keV was achieved in the T–3 machine; the pulse duration was 20 ms (ref. 5). The density is in the region 2 to 5×10^{13}, giving a value of $n\tau$ of 10^{12}, the largest yet achieved anywhere. The result was surprising, according to conventional theory, because such temperatures are not accessible by Joule heating with classical plasma conductivity. The resistivity of the Tokamak turned out to be 5 to 10 times the classical value and this has been explained in terms of a plasma turbulence. There is a critical limit to the current that can be passed through the plasma (in terms of the longitudinal magnetic field), which is such that the spiral executed by the resultant magnetic field does not close on itself in one circuit of the torus (Kruskal-Shafranov limit). This implies a very low value of β for the plasma. A visit by Artsimovich to the United States convinced physicists there of the validity of the results—the first time thermonuclear temperatures have been achieved in a slow, low-β system. This produced a somewhat surprising landslide toward Tokamaks in the United States with the result that five machines of differing designs have been authorized (at Oak Ridge National Laboratory, Princeton Plasma Physics Laboratory, Austin, Texas, MIT and Gulf-General Atomic at La Jolla). In the meantime, the construction of a much larger Tokamak, T–10, has commenced in the USSR.

The Tokamak is a very real experimental advance which reflects great credit on Artsimovich and co-workers. It is far from clear how the Tokamak can be extrapolated to a reactor, as the Russian physicists readily concede. For one thing the present method of Joule heating will not continue from 0.4 keV to the required 10 keV even with anomalous resistivity although supplementary heating processes, such as ion cyclotron heating, have been proposed. It is hard to imagine that with the present low value of β ($\sim 10^{-3}$) a reactor could be economic, so some method of confining stably more plasma and exceeding the Kruskal–Shafranov limit seems to be needed. The plasma density can also be increased by reducing the torus aspect ratio—making it fat. At the most recent Fusion International Conference at Madison, Wisconsin, in June 1971, a most ingenious proposal was made for self-driving of the longitudinal plasma current by the outward diffusion of new fuel injected into the axis. This may greatly reduce magnetic core requirements, and even offers the possibility of a steady state reactor. Other basic problems of extrapolating Tokamak into a reactor arise from the presence of the multiplying blanket and from synchrotron radiation by the hot electrons. The 1 m thick blanket must be interposed between the heavy torus windings—which are too thick to transmit neutrons—and the plasma. The presence of the 1 m standoff weakens the stabilizing effect of the wall so other stabilizing means are being sought; a scale size for a reactor in the 10,000 MW_e range is thus established. Fig. 2 is a Russian schematic drawing of a Tokamak power reactor showing the scale and general appearance; the heat exchangers, turbine, injection and processing auxiliaries are not shown.

The synchrotron radiation flux from the electrons of the plasma in a magnetic field has been estimated theoretically but the flux has not yet been observed experimentally. The radiation is an individual process and therefore emitted at a rate proportional to the density—by contrast with the thermonuclear fusion reaction itself which proceeds at a rate proportional to the square of the density. Consequently high densities favour the desired fusion over the undesired radiation. In a reactor situation, synchrotron radiation increases as β^{-3} and becomes the dominant process at values of β less than about 0.01. The subject of synchrotron radiation is theoretically difficult and tends to have been treated superficially in reactor studies. The radiation will have a wavelength in the region 0.01 cm and this is easily reflected by metal mirrors with an efficiency of 99%. By completely surrounding the plasma with such a reflector, the synchrotron losses can be greatly reduced though the radiation intensity inside the shield rises above its previous value. The problem is that, quite apart from the effect that the enhanced radiation will have on the stability of the plasma it is certain that engineering requirements pumping ports and so on, will make it very difficult to achieve 99% perfection in the reflecting enclosure. A theoretical calculation for the Tokamak indicates that synchrotron radiation loss would be a significant factor in the energy balance for a Tokamak without reflectors[6].

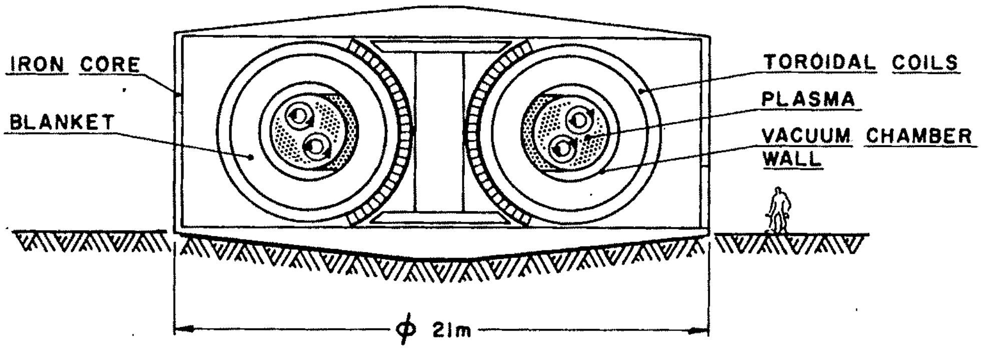

Fig. 2 Tokamak reactor. Fuel, D+T; thermal power, 5 GW; electrical power, 2 GW; major plasma diameter, 14 m; maximum magnetic field, 100 kgauss; plasma density, 3×10^{14} cm^{-3}; containment time, 0.7 s; $\beta = 0.3$. Two of many ion orbits are shown in the plasma region. (After Golovin, "Energy 70", Las Vegas, 1970.)

Direct Conversion

Most (~14 MeV) of the total Q of 18 MeV associated with the DT reactions appears in the form of neutron energy. This

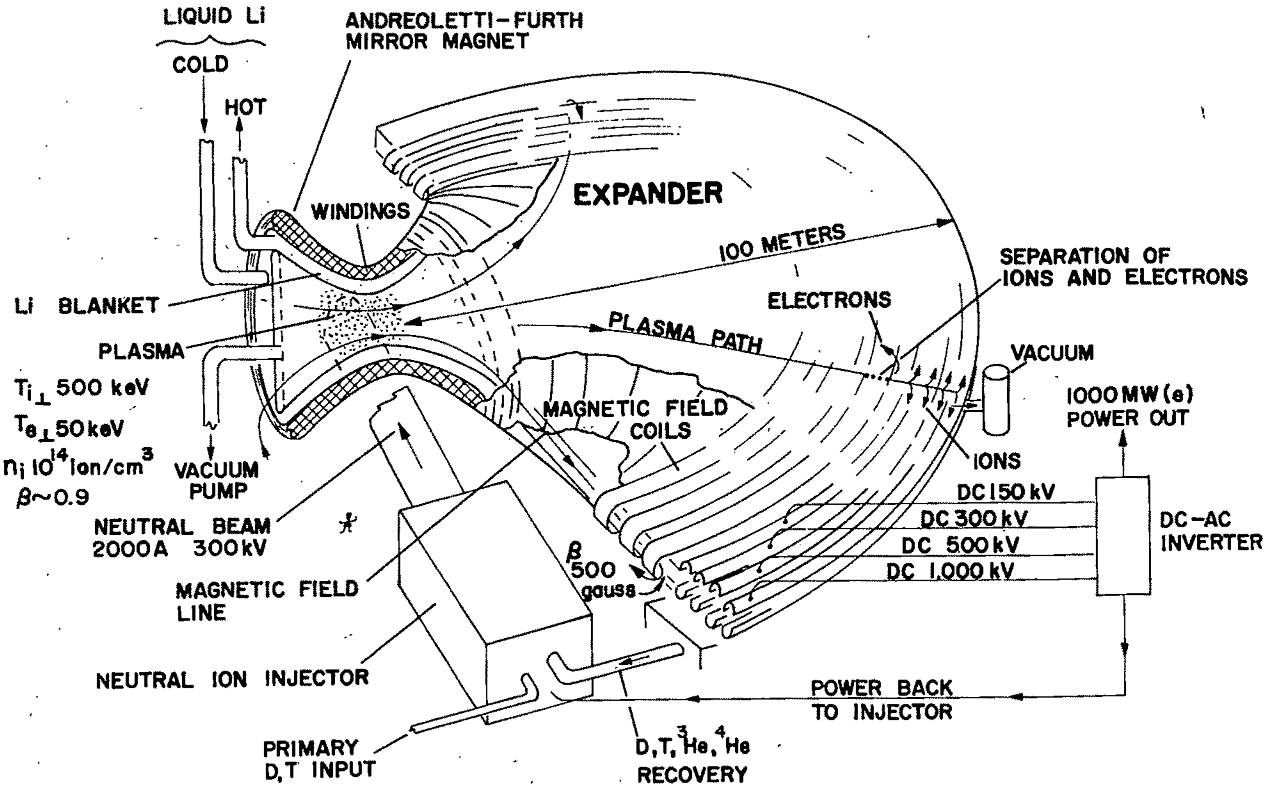

Fig. 3 Direct conversion mirror fusion reactor.

energy can be utilized only by depositing it in a target as heat and passing the heat through a thermal cycle (for example, a Carnot cycle). The efficiency of a Carnot cycle between upper temperature T_1 and lower temperature T_2 is $(T_1 - T_2)/T_1$ and, for practical upper temperature ~750 K and lower temperatures 373 K, this value is about 0.3 to 0.4. This efficiency appears in the Lawson break-even equation for $n\tau$ as $(1-\varepsilon)/\varepsilon$ or, with $\varepsilon = 0.3$, a factor ~2.3. In the DD reaction, only 38% of the Q of ~4 MeV appears in the neutron, so that most of it is evident in the form of α particles, protons and ^{3}He nuclei. In the case of the D^{3}He reaction, all the energy of the reaction is emitted as charged particles. Now although the neutron energy can only be converted into power by the low efficiency thermal cycle described previously, charged particle energy could, in principle, be converted much more efficiently either by allowing the plasma of charged particles to do work on a magnetic field directly or by separating the charged components of the plasma and discharging them into conductors, that is, direct conversion. In either case, the upper temperature of the Carnot cycle becomes, in effect, the plasma temperature $\sim 10^8$ K. Taking T_1 as 10^8 K, this gives a value of ε of 0.999, so $(1-\varepsilon)/\varepsilon \sim 10^{-3}$; this brings the Lawson criterion $n\tau$ down from its previous value by a factor of 2,300. According to the calculation for this ideal, DD fusion with direct conversion would be easier, in terms of $n\tau$, than DT fusion without it.

Post[7] has made the ingenious suggestion that the exhaust plasma from a mirror machine should be expanded by a large factor. This has the effect of converting the initially random motion of the plasma into a quasi-ordered beam, that is, an isentropic expansion. The beam of plasma is separated into its ion and electron components by magnetic deflexion, and the charges in the two components collected in stages to provide high voltage d.c. power. The expander is of considerable size (Fig. 3) but the elimination of the tiresome and inefficient heat exchanger-boiler-turbine combination characteristic of other fusion reactors, and the achievement of a power plant with no moving parts, would be more than worth while.

Not only does the mirror machine have to operate at a much higher ion temperature ($\gtrsim 100$ keV) than other systems but the electron temperature has to stay low ($\lesssim 30$ keV) and decoupled from the ions; this is a thermodynamic disequilibrium which invites instability. If instability should occur, then the electron temperature will rise, bringing trouble from increased synchrotron radiation. Furthermore, in mirror-machine reactors the fraction of plasma burn-up during one passage of the plasma through the machine is small so a large amount of energy (compared with the useful output energy) has to be recirculated—that is, plasma is reinjected into the machine. This means that the achievement of a positive power balance depends critically on a very high efficiency, >90%, in the stages—output beam-to-electricity converter and electricity-to-input-ion beam accelerator—through which the large recirculating power passes. These values are based on a classical mirror confinement time. There is evidence that the loss out of the mirrors is 10 to 15 times faster than this because of the effect of theoretically predicted instability. If this instability cannot be overcome, the stage efficiency requirement will become even more stringent—to the extent, possibly, of being unrealizable.

It is a most interesting idea whose application may extend to the thermonuclearly more efficient high β, open-ended, linear Scylla-type reactor. This is already capable of yielding a positive power balance using a DT fuel at 10 keV temperature and the usual low 0.3 efficiency for ε. If direct conversion, with an efficiency $\varepsilon = 0.9$, were applied, $n\tau$ could be lowered by a factor of ~20 to 30—which might yield a positive power balance even with DD. The blanket could then be omitted and the whole system made much simpler.

Scylla-Scyllac θ Pinch

Plasma in a long tube is subjected to a rapidly rising longitudinal magnetic field. This has the effect of first shocking the plasma, and then adiabatically compressing it. The elegant aspect of this approach is that the heating is applied directly to the ions, where it is needed; the heating is not resistive (which would heat the electrons first) and does not fail when the temperature is very high and the plasma is exceedingly con-

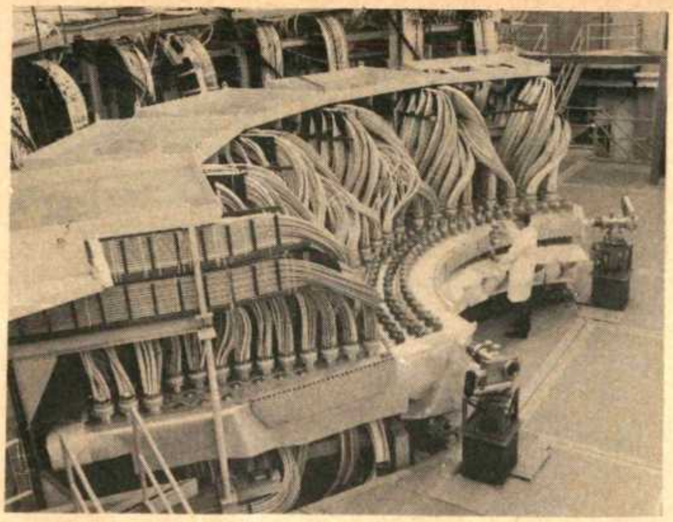

Fig. 4 Completed 120° arc of the Los Alamos Scyllac toroidal θ pinch.

ductive. Unlike many other approaches, the hotter the plasma gets the better behaved it has been found experimentally to become. This device in its early form (Scylla I) produced the first laboratory thermonuclear reaction in 1957, although it was not until 1961—after many experiments—that the thermonuclear character was established beyond doubt. Achievements with Scylla IV are T_{ion}, 5 keV; n, 5×10^{16} ion cm^{-3}; τ, 5 μs; $n\tau$, 2.5×10^{11} ion cm^{-3} s; (β (max) ~ 0.9; β (av) ~ 0.3).

Although the Scylla θ pinch was originally conceived[8] only as an experiment to make thermonuclear plasma, it was later shown[9] that, in principle, it could become a reactor. The idea was to make the compression coil thin enough to be essentially transparent to the 14 MeV neutrons. This allows the T regenerating blanket of thickness 1 m, which is also the flowing Li-Be heat removing fluid, to be outside the coil.

The temperature achieved is already within a factor of two of the target temperature for a reactor, and there is no obvious difficulty in raising it further. At present, the confinement time ~5 μs is determined by free escape of the plasma from the ends of the compression coil. There are two ways to extend this time. One is to close the compression coil on itself to form a torus. This distortion introduces field gradients, disequilibrium, and calls for entirely new countermeasures to give stability and to hold the plasma in the centre of the tube. It is not yet known whether stability will be obtainable statically or whether dynamic or servo methods may have to be used. In its toroidal form, this device is known as Scyllac (Scylla-closed), and it is under construction at Los Alamos (Fig. 4). It will be some years before it is completed and, ideally, it is expected to increase $n\tau$ by a factor of up to 50 from the present value of 2.5×10^{11}.

Alternatively, it is possible to increase confinement time by lengthening the present straight system. This certainly has the merit of simplicity and the magnetic field is uniform. To reach a value of $n\tau$ appropriate to a reactor by this method alone would, however, require a length of several km. But it may be possible to restrict the loss from the ends and a roughening procedure in the magnetic field has given some theoretical support for optimism, in essence giving the plasma flow Knudsen[10] characteristics. A loss reduction by a factor x reduces the reactor length by the same factor. Electron synchrotron radiation is likely to be much less of a problem in θ pinches because they are high n, high β devices. The straight θ pinch reactor has a simple geometry (Fig. 5) and involves the least extrapolation beyond present plasma physical knowledge and experience. The ends form a natural way of disposing of the plasma, and may even provide extra power by direct conversion or by a pulsed magnetohydrodynamic generator.

The great length of the reactor in its unstoppered form makes is impractical and, above all, the engineering problem of supplying economically the enormous pulse power (proportional to the length) is unresolved. Condensers are also too

expensive but rotating superconducting generators[11] have been proposed.

The toroidal Scyllac is more radical in concept and more liable to instability but has lower pulse power requirements. The serious problem of feeding plasma in and removing it without damage to the inner wall has not yet been tackled.

Laser Heated DT Pellet

The density of solid DT at 4 K is 6×10^{22} atom cm^{-3}. If a pellet of radius r could be heated instantaneously to 10 keV, a strong thermonuclear reaction during the rapid expansion (velocity $\sim 10^8$ cm s^{-1}) would take place. The effective confinement time will be $\sim r/10^8$ s.

From Fig. 1, it can be deduced that r would have to be about 1 mm to reach reactor status. Expressed alternatively, the input energy is proportional to the volume r^3, but the thermonuclear output energy is proportional to this volume and the time (one more factor of the radius) or r^4. Thus there has to be a value of the radius such that the output exceeds the input. According to elementary plasma theory, at the density of 6×10^{22}, radiation from known lasers would be below the plasma cut-off frequency for that density and would be reflected. It is far from clear whether this holds true at the radiation intensities existing at a laser focus. Further, a pre-preparation of the pellet surface density can be envisaged, which would increase the laser energy absorption at the surface. At first, in the mid-1960s, it seemed to many of us that such ideas were hopeless for power production, for the pumping efficiency of, say, Nd glass lasers was $<1\%$—which imposed a hundred-fold adverse energy factor at the outset. More recently, however, the CO_2 laser has achieved an efficiency $>20\%$ (theoretical limit $\sim 40\%$), which might just be acceptable.

The reactor that might develop from these ideas (Fig. 6) is the model of simplicity—no magnetic fields, no stability. In fact instability is an advantage, for it may help the heating. The pellet is dropped into a boiler which is strong enough to withstand the explosion and the inner walls of which consist of a rapidly flowing 1 m layer of liquid lithium, which acts as the tritium regenerator and carries off the heat to the exchanger. There should be no trouble about heating of the wall, a sensitive point in all other fusion reactors, as it is constantly renewed.

The energy input and output are sensitive functions of the pellet radius at break-even. If the laser energy input for positive energy balance turns out to be, say, 10^5 J—which is some distance beyond present laser practice but imaginable—and the energy (thermal) output is, say, 10^7 J—equivalent to a few pounds of TNT which could easily be confined, even repetitively in a boiler of reasonable dimensions—the reactor will be very attractive. But an increase in the break-even radius of, say, a factor of ten would increase these figures by a factor of 10^3; this would place the system far from reality and would necessitate a boiler which could withstand the equivalent of several tons of TNT exploding repetitively—it would be beyond present engineering practice. Clearly it is very advantageous to increase n because this diminishes the τ for break-even in inverse proportion, which in turn brings down the required input energy by the same proportion to the third power. Any way of slowing down the expansion rate pays off equally handsomely.

It should be obvious that there are very rewarding directions for the application of ingenuity to this problem. And there is even an alternative possibility to the laser for the heating source—a pinched-down beam of relativistic electrons.

There are two other interesting problems. The laser radiation must be admitted into the boiler through some aperture and, clearly, the explosion must not destroy the optics. There is very little time between the admission of the radiation and the impact of the explosion shock-wave on reaching the walls, so the manipulation of a trapdoor would be very difficult. Thin metallized plastic expendable mirrors spring to mind, however. Finally, factors of reactor economics common to all fusion reactors show up with great clarity in this case. One kWh (electric), $=3.6$ MJ, can be generated currently for 0.3 to 0.5 cents and therefore that is all that can be spent per shot (for the 10^7 J case above) to cover the laser pumping, plant, salaries, processing, DT and cryogenics. It will obviously have to be a very efficient operation. It is too early to guess how the DT pellet reactor will fare in the fusion reactor race. Superficially it looks very good—but this may be because it is also the newest. In France, this approach is being studied at Limeil and in the United States at Livermore, Los Alamos, and Oak Ridge. At the Lebedev Institute, Moscow, they are also thinking along similar lines.

All fusion reactor approaches have unsolved problems and their problems differ greatly in kind. Nonetheless, it seems to me very likely that out of the diversity, one at least will succeed. Nuclear energy is certainly essential for the future of mankind and, although fission is solving some of the energy problems, fusion will in many ways be far more satisfactory. But it will probably not become competitive for thirty years.

This work was performed under the auspices of the US Atomic Energy Commission.

Acetylcholine Receptors in Muscle Fibres

R. MILEDI & L. T. POTTER
Department of Biophysics, University College, London

There are calculated to be approximately 10^9 acetylcholine receptors in a frog muscle fibre. This has important implications for theories concerning the nerve to muscle transmission mechanism.

THE transmission of impulses from nerve to skeletal muscle fibres of vertebrates is mediated by the release of a transmitter—acetylcholine (ACh)—from the motor nerve endings. After diffusing across a narrow synaptic cleft, the ACh molecules react with a specific "receptor" in the muscle fibre membrane, and consequently the ionic permeability of the membrane is greatly increased. While the process of transmitter release has been relatively well studied[1], our knowledge of ACh-receptors is, so far, fragmentary.

Intracellular recording and micro-ionophoretic application of ACh have established that the ACh-sensitivity of normal muscle fibres is maximal in the region of neuromuscular contact and falls sharply therefrom[2]. Such experiments demonstrated the pattern of distribution of the ACh-receptors but not their number, which can apparently now be obtained with the use of snake toxins.

It has long been known that several snake venoms have a curare-like action[3]. Chang[4] showed clearly that the venom from a Formosan snake (*Bungarus multicinctus*) abolished neuromuscular transmission by blocking the action of ACh, apparently in an irreversible manner. Chang and Lee[5], and Lee, Tseng and Chiu[6], subsequently established that a subfraction of this venom blocked neuromuscular transmission by combining with a site on or near ACh-receptors. We have confirmed and extended their work.

Twelve pure proteins were isolated from the dried venom of *B. multicinctus* (details to be published elsewhere). The most prevalent of these (20–25% of the protein of the venom) is a basic protein with a molecular weight of 8,000; it probably corresponds to the "α-bungarotoxin" of Chang and Lee[5], and was used for our experiments.

ACh-receptors in Normal Muscles

When α-bungarotoxin (α-BuTX) was added to Ringer solution bathing frog or rat muscles, neuromuscular transmission was blocked. Nerve impulses continued to invade the nerve terminals and release ACh, but the action of ACh on the postsynaptic membrane was progressively reduced. Fig. 1 illustrates the effect of 10^{-6} g/ml. of α-BuTX on the amplitude of the end-plate potential (e.p.p.) which can be taken as an index of transmitter action on the muscle fibre membrane. At zero time the bath was changed to one containing the toxin and, when the microelectrode was reinserted into the fibre a few minutes later, the e.p.p. was already reduced. Subsequently the e.p.p. amplitude continued to fall, approximately exponentially, with a half time in this case of about 2.25 min. The sensitivity of the end-plate to ionophoretic or bath application of ACh is concomitantly reduced.

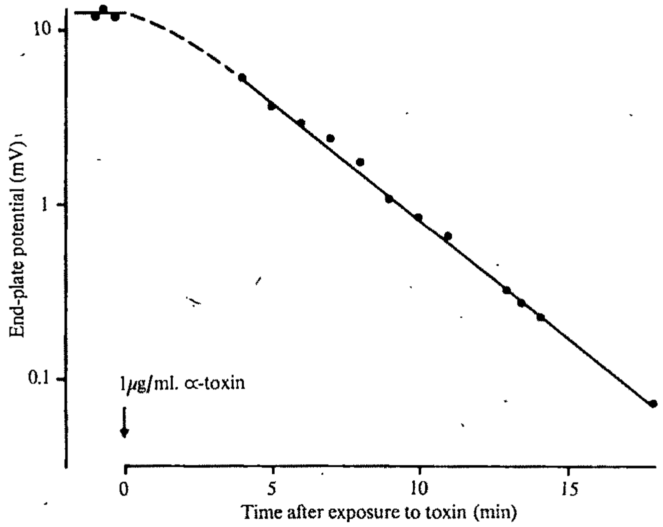

Fig. 1 Effect of α-BuTX on the amplitude of end-plate potentials from a surface end-plate in a frog sartorius muscle. Each point is the average of twelve potentials.

The time-course of blockade was concentration-dependent, and also varied appreciably from fibre to fibre within a muscle. End-plates deep within the muscle took longer to block than surface end-plates, but with 10^{-6} g/ml. α-BuTX all end-plates of frog sartorius muscles ceased to transmit impulses in 1–2 h. This variability is very likely due to limitations in the access of the toxin to the end-plates, either because of diffusion barriers or because the toxin reacts at other sites on its way to the end-plates. In some experiments α-BuTX was applied ionophoretically. This makes it possible to block only a small part of an end-plate, and the rate of block is then much faster than shown in Fig. 1.

Several muscles were exposed to 10^{-5} g/ml. of α-BuTX for about 2 h, and were then washed for several hours at room temperature, with no sign of recovery of ACh-sensitivity. Washing was then continued at 3–4° C and even more than 8 days later the muscle fibres remained excitable but there was still no recovery of either neuromuscular transmission or sensitivity

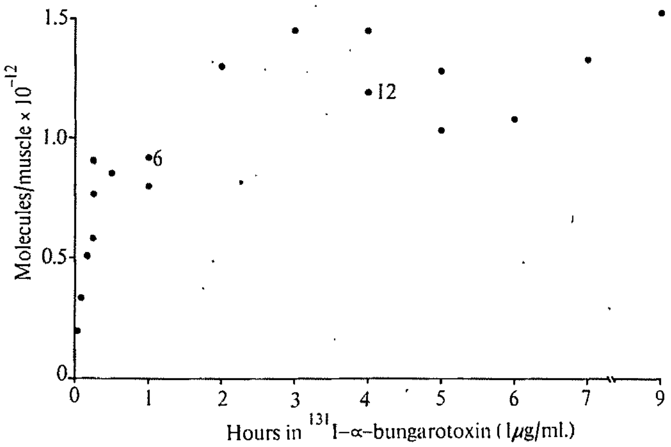

Fig. 2 Saturation of toxin-binding sites of frog sartorius muscles. Muscles were exposed to ^{131}I-α-BuTX for the periods indicated; then washed and assayed for radio-iodine (see text). Points represent single muscles or mean values of groups of muscles the number of which is shown.

to acetylcholine, which shows that blockage of ACh-receptors by α-BuTX is, for practical purposes, irreversible.

To study its binding to cholinoceptive tissues α-BuTX was labelled[7] with ^{131}I. Such labelling consistently gave an initial specific activity (of 23,000 Ci/mol) with no observable loss in the ACh-receptor blocking activity of the toxin. Muscles were exposed to the labelled toxin at 20° C for various times and then washed free of unbound toxin by repeated bath changes for about 24 h at 4° C. The tissue was then dissolved in an alkaline solvent ('Soluene', Packard), and the amount of ^{131}I was determined by liquid scintillation spectrometry. Corrections for isotopic decay were made by measuring the activity of the stock solution of ^{131}I α-BuTX at the same time as a series of muscle samples.

The time-course of toxin-binding to frog sartorius muscles is shown in Fig. 2. Binding increased during the first 2 h at a rate comparable with that of neuromuscular blockade, and then reached a plateau level of 1.2×10^{12} molecules of toxin per muscle (mean of twenty values obtained after 2 h). Similar experiments with diaphragms of rats and mice gave respective values of 4.7×10^{11} and 1.6×10^{11} toxin-binding sites per hemidiaphragm (means of twenty-eight and six respectively).

If the amount of bound toxin is to be used to estimate the number of ACh-receptors or to mark them for subsequent isolation, it is important to determine the specificity of the binding. One measure of the specificity of toxin-binding to receptors is its localization on the muscle fibres. Using autoradiography, Lee, Tseng and Chiu[6] have shown that in rat most of the label is in the end-plate region. To obtain a more quantitative estimate of the localization of binding, we have divided muscles into portions, some of which were practically free of end-plates. In the frog sartorius, "end-plate free" portions (amounting to about 20% of the wet weight of the muscles) had an average of 2% of the total counts (mean of twenty-four muscles); and even some of this binding is probably still associated with the ACh-receptors which are known to exist in "end-plate-free" regions[8,9]. In the rat diaphragm end-plate-free portions accounted for five-sixths of the muscle and had about 10–15% of the total radioactivity. All this shows that non-specific binding of the toxin is not a large complicating factor.

As most of the toxin is bound at end-plate regions, the plateau level of binding (Fig. 2) may be used to estimate the number of toxin-receptive sites per end-plate. In the frog sartorius muscle, which has about 500 muscle fibres and two to four end-plates per fibre[10,11], the number of toxin-receptive sites per end-plate is about 10^9. The corresponding number for the rat hemidiaphragm which has about 10^4 singly-innervated fibres[12] is about 4.7×10^7 sites per end-plate. Assuming the same number of fibres in the mouse hemidiaphragm gives a value of 1.6×10^7 sites. The last figure is several times larger than the number of curarine-binding sites found by Waser[13], perhaps partly because curarine, a bisquaternary ammonium compound, blocks only half of the toxin-binding sites (see below). In this context, it is interesting that Changeux, Kasai and Lee[14] have found roughly twice as many binding sites for α-BuTX as for decamethonium (another bisquaternary amine) in the electric tissue of eels.

ACh-receptors in Denervated Muscle

After denervation the entire muscle fibre membrane develops ACh-receptors with properties resembling in most respects those of the junctional receptors[8,11,15]. They are, however, less sensitive to curare[16], and it was therefore important to find if the new receptors are also blocked by α-BuTX. The ACh-sensitivity of muscle fibres was measured[11], some 6 mm away from the end-plates, in a muscle which had been denervated for 28 days. After 3 h in α-BuTX (10^{-6} g/ml.) the ACh-sensitivity had fallen by more than 1,000 times, a clear indication that α-BuTX also blocks the newly developed ACh-receptors. Accordingly, the amount of bound toxin was also increased after denervation. The number of toxin sites per muscle increases progressively (Fig. 3), reaches a peak and then starts to decrease, presumably because the muscle fibres atrophy and decrease in size and number on account of the prolonged denervation.

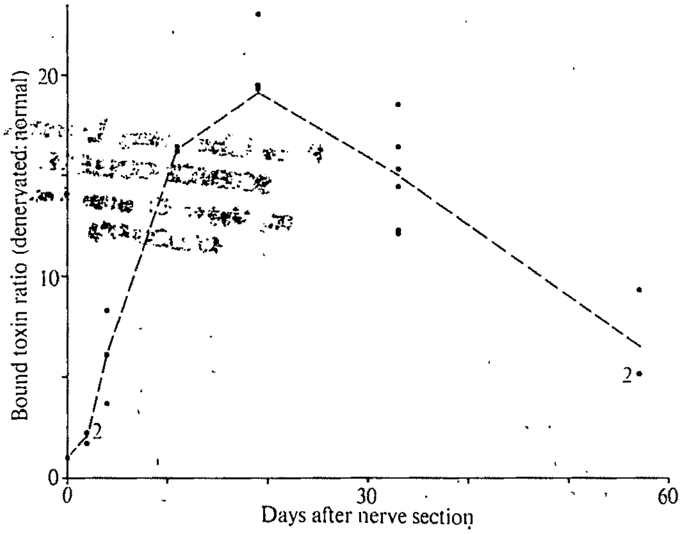

Fig. 3 Effect of denervation on number of binding sites. Left diaphragm muscles were denervated by section of the phrenic. At the indicated times after denervation, the muscles were exposed to labelled α-BuTX, 1 μg/ml., for 4 h at 20° C, then washed and assayed for radioactive iodine. The normally innervated right hemidiaphragms and one sham operated left hemidiaphragm (point at 0 days) bound a mean of 3.95×10^{11} toxin molecules/hemidiaphragm. The ratio of toxin-binding sites in denervated to normal hemidiaphragms is shown on the ordinates.

Just as the ACh-sensitivity spreads to the entire muscle fibres, so does the binding of α-BuTX[6]. This was shown by incubating strips from a denervated diaphragm and from its opposite innervated control muscle in α-BuTX. After washing, the strips were fixed in glutaraldehyde, as previous experiments showed that all the bound toxin was retained after various fixative procedures. Subsequently, the strips were divided into 2 mm segments and their labelled toxin content measured (Fig. 4). The increase in toxin bound to extra-junctional regions is large and, as there is no detectable ACh-sensitivity far from the end-plates in the normally innervated diaphragm[2], it seems likely that most of the small amount of toxin bound at these regions in normal muscles is unspecific. Nevertheless, after denervation the number of receptors in these regions increases by at least 200 times.

As extra-junctional regions develop a high ACh-sensitivity after denervation, and the ratio of total surface membrane to synaptic membrane areas is roughly 300, it is puzzling that the overall increase in toxin-receptive sites is only about twenty times. Perhaps the increase in receptors is not larger because, during the first weeks after denervation, the ACh-sensitivity of the extra-junctional region does not reach the level of sensitivity at the end-plate[8], while subsequently the muscle becomes atrophic. Also, the juxta-synaptic region already has ACh-receptors[2] so after denervation the increase in receptors in this region will be comparatively smaller.

Fig. 4 Distribution of bound toxin along normal and denervated muscle fibres from the rat diaphragm. The end-points in the denervated strip have less toxin bound because of tapering of the strips.

After regeneration of neuromuscular synapses the ACh-sensitivity of extra-junctional regions again becomes very low[17] and, as expected, the number of toxin-receptive sites is also decreased. For instance, two muscles were studied 71 days after crushing the phrenic nerve. With this procedure, the muscle fibres are denervated for approximately two weeks, and during that time they develop the generalized sensitivity to ACh, and are then rapidly reinnervated without allowing the muscle to become very atrophic. After exposure to toxin the reinnervated muscles had a mean of 5×10^{11} molecules of toxin per hemidiaphragm and a regenerated/normal ratio of 0.97, values similar to those observed in normal muscles.

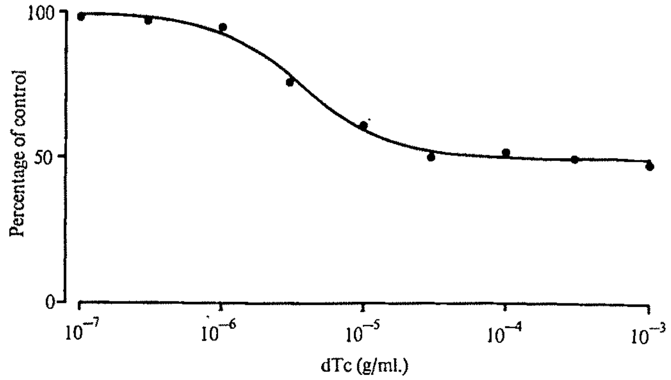

Fig. 5 Effect of *d*-tubocurarine (dTc) on binding of α-BuTX. One of each of nine paired frog sartorius muscles was equilibrated for 2 h in *d*-tubocurarine at the specified concentrations, and then exposed to α-BuTX while still in the dTc. All muscles were exposed to 1 μg/ml. ^{131}I-α-BuTX for 1 h and then washed for 1 h in 10^{-4} g/ml. dTc without toxin to reduce further binding of toxin during the washing period. Ordinates represent the amount of toxin bound by the muscle incubated in dTc as a percentage of that of its paired muscle incubated without prior or simultaneous exposure to dTc.

Protection of Toxin-binding Sites by Curare

Chang[4] and Chang and Lee[5] have shown that *d*-tubocurarine (dTc) protects muscles against the postsynaptic action of the venom from *B. multicinctus*, and dTc would therefore be expected to reduce the binding of α-BuTX to muscles. To estimate the degree of this protection, frog sartorius muscles were equilibrated in various concentrations of dTc and were then exposed in addition to labelled α-BuTX (10^{-6} g/ml. for 1 h). The paired control muscle were separately exposed to the toxin without previous treatment with dTc. Fig. 5 shows that dTc decreased the binding of α-BuTX, and protected the ACh-receptors. With dTc concentrations higher than 10^{-5} g/ml. some muscle fibres still gave action potentials to nerve stimulation after both the toxin and dTc had been washed out.

An unexpected finding was that toxin-binding was not reduced below 50%, even with the highest dTc concentration used (Fig. 5). There seem to be, therefore, two classes of toxin binding sites, only one of which can be blocked by dTc at the concentrations studied, but the reason for this is not yet entirely clear. It could be that half the toxin binding sites are not ACh-receptors. This does not, however, seem very likely because the unspecific binding outside the end-plate is negligible, and because the binding of α-BuTX can be reduced further by ACh itself. A more plausible explanation is that there are two different membrane molecules, both capable of reacting with ACh and α-BuTX, but only one with a high affinity for dTc. While the pharmacological competition between ACh and dTc suggests that both act on the same site, it is also conceivable that there is a dTc-receptive molecule which does not have ACh-reactive sites, but which blocks the action of ACh through allosteric interactions. Differences in the distribution of the dTc-receptive sites could explain the lower dTc-sensitivity of extra-junctional receptors after denervation[16] and also explain why the binding of radioactive curarine does not increase much after denervation[13].

Desensitized Receptors

During prolonged exposure to a drug, the responsiveness of many tissues to the same or similar drugs is greatly reduced. In the case of skeletal muscles, Thesleff[18] has shown that during continuous application of ACh, depolarization of muscle fibre membranes is not maintained (the resting potential gradually returns to its normal level, even though the ACh is still present). Thus muscle fibres become refractory to the action of ACh.

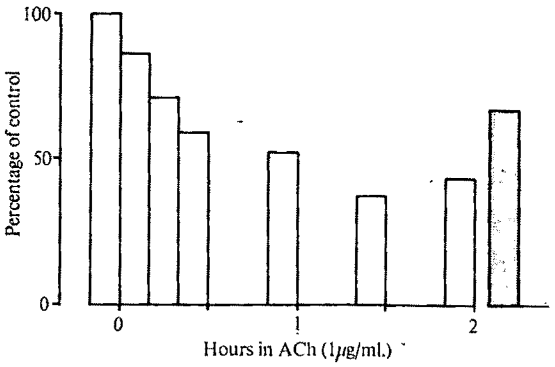

Fig. 6 Effect of desensitization of ACh-receptors on binding of α-BuTX. One of each pair of muscles was exposed to toxin (2 μg/ml. for 10 min) after being in ACh (AChCl+neostigmine HBr both 1 μg/ml.) for the indicated times. The other muscle from each pair was exposed to the toxin without prior treatment with ACh and served as control. All muscles were placed in ACh for a total of 3 h. One muscle (shaded bar) was removed from the ACh after 2 h and washed repeatedly for 5 min before being exposed to toxin, after which it was returned to ACh for 1 h.

This process of "desensitization" was later studied in more detail by Katz and Thesleff[19] and others, and to explain it several hypotheses have been proposed[19–23].

In principle, the loss of action of ACh during sustained drug application could occur at any step from the ACh+receptor combination to the development of the ionic current responsible for membrane depolarization. An irreversible antagonist such as α-BuTX might produce some clues to this problem. For instance, if desensitization were to involve changes in the later steps, subsequent to the combination of ACh with the receptors, then the binding of α-BuTX in desensitized muscles might be expected to be the same as in a normal muscle. Alternatively, the change might occur at the receptor level and perhaps reduce the binding of toxin.

To examine these possibilities, muscles were exposed to ACh (10^{-6} to 10^{-4} g/ml.) in the presence of neostigmine methylsulphate (10^{-6} g/ml. to prevent hydrolysis of ACh by cholinesterases). Acetylcholine caused a marked and immediate depolarization of the end-plates, followed by a gradual recovery of the resting potential. One to three hours after commencing the application of ACh, the muscle bath was rinsed several times with normal Ringer to wash out the ACh, and approximately 10 min later the muscle was exposed to α-BuTX (10^{-5}—3.6×10^{-5} g/ml.) for 5–10 min, and rinsed again several times. When these muscles had recovered from the desensitization caused by ACh, miniature end-plate potentials could be recorded from many surface fibres, and stimulation of the nerve evoked end-plate potentials which sometimes triggered muscle action potentials, in spite of having been exposed to the toxin. In contrast, muscles which had not been desensitized by ACh were blocked by the same treatment with α-BuTX. These experiments indicated clearly that desensitized muscles are less susceptible to the blocking action of α-BuTX, and further experiments were carried out to see if the binding of toxin was also reduced.

The binding of α-BuTX to muscles exposed to ACh for various times is progressively decreased as the muscles become desensitized (Fig. 6). During simultaneous exposure to ACh and α-BuTX, some competition for receptive sites may occur but this, however, would presumably have a faster time course than the decrease in binding illustrated in Fig. 6. A further indication that the decrease in binding is due to desensitization of receptors is that binding was still reduced 5 min after removing the ACh (shaded bar in Fig. 6). In other experiments it was found that a higher concentration of ACh (10^{-4} g/ml.) already reduced toxin binding maximally (81%) when applied simultaneously with the toxin, and that full recovery of binding occurred with a time course roughly parallel to re-sensitization of the muscle fibre membrane.

In their model of desensitization, Katz and Thesleff[19] proposed that receptors can exist in either an active or a refractory form. Their experimental results were best fitted to a scheme in which the affinity of the drugs for desensitized receptors was much higher than for resting receptors. More recently, Rang and Ritter[24] have found that certain bisquaternary drugs have a preferential affinity for desensitized receptors. It seems clear, however, that desensitization of the muscle fibre membrane by ACh reduces its ability to bind α-BuTX but it is not known how this is brought about. There are, of course, several possible explanations. For example, it could be that ACh molecules remain on the receptor for many seconds—instead of merely a fraction of a second—and that during that time receptors are unable to combine with the toxin. Another possibility is that activation of a receptor by ACh leads to a slowly-reversible change in the structure of the receptor, a change which prevents further combinations with ACh or toxin molecules.

Solubilization of the Toxin-binding Material

^{131}I-labelled α-BuTX saturates binding sites in washed fragments of membranes from *Torpedo* electric tissue, and the toxin-tagged material can be "solubilized" (brought into a form which does not sediment during ultracentrifugation for several hours) with the non-ionic detergent, 'Triton X-100' (ref. 27).

Preliminary studies of the toxin binding sites of frog sartorius muscles by the same procedures (Fig. 7) indicate that the labelled substances in muscles and electric tissue are very

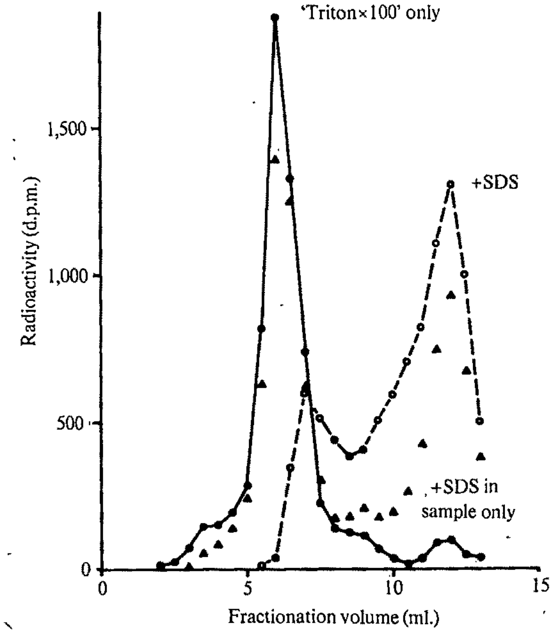

Fig. 7 Ultracentrifugation of toxin-binding material. Twelve frog sartorius muscles labelled with ^{131}I-α-BuTX were homogenized in fifteen times their weight of 20 mM sodium phosphate buffer, *p*H 7.5. Large particles including cell membranes were sedimented at 10^6g-min, and were extracted with 3 ml. of 1.5% 'Triton X-100' in 20 mM buffer for 2 h at 4° C. After recentrifugation, 0.5 ml. samples of the clear extract ±2.5 mg sodium dodecyl sulphate (SDS) were centrifuged over linear density gradients (5–25% sucrose in 20 mM buffer+1% 'Triton X-100' ±0.5% SDS; 12.5 ml. in Spinco SW 40 Ti tubes) for 22 h at 39,000 r.p.m. Results are given as d.p.m. ^{131}I per 0.5 ml. fraction; volumes are measured from the bottom of each centrifuge tube. The mobility of the toxin-binding material in 'Triton X-100', and its partially-reversible disaggregation in SDS, appear the same as that previously seen with toxin-binding material from *Torpedo* electric tissue[27].

similar. After toxin-labelled sartorius muscles were disintegrated with a high-speed blender in dilute buffer, 93% of the ^{131}I sedimented with cell particles during ultracentrifugation. Extraction of the sediment with 'Triton X-100' permitted quantitative recovery of the labelled substance in the supernatant fluid after recentrifugation. Examination of this material by density gradient centrifugation indicated that most of it sedimented in one peak, exactly as did similarly-treated toxin receptor from *Torpedo* electric tissue (compare Fig. 7 with Fig. 4*B* from ref. 27). In addition, SDS reversibly disaggregated the toxin-tagged material from muscles. These results indicate the feasibility of extensive purification and characterization of the muscle receptor for α-BuTX.

Toxin-receptive Sites and ACh-receptors

The correspondence between the pattern of ACh-sensitivity and the localization of bound toxin, in normal and denervated muscles, already indicates a strong similarity between ACh- and toxin-receptive sites; but confirmation that they are identical will have to await the elucidation of the detailed structure of the receptor. It should, however, be mentioned here that the effects of dTc, and in particular the experiments on muscles desensitized by ACh, suggest that ACh and α-BuTX act on the same site, or on sites close enough to allow interactions.

On the assumption that one toxin site is equivalent to one ACh-receptor, there are about 10^9 ACh-receptors in a frog muscle fibre. This is only a preliminary estimate, but already some interesting points emerge if considered in relation to the recent suggestion by Katz and Miledi[25,26] that the depolarizing action of ACh is built up of elementary events with a calculated amplitude of 0.22 μV.

The neural transmitter is released in quanta, each of which would evoke about 2,000 elementary events; and a nerve impulse, releasing say 300 quanta, would evoke 6×10^5 elementary events. The question is still open whether one elementary event is caused by the activity of one or more receptors; but assuming, for the time being, that one active receptor is equivalent to one elementary event, a nerve impulse would activate less than one thousandth of the available receptors. Thus there seems to be a large number of spare receptors, even if each elementary event were to require the activation of ten receptors, which is not likely.

During external application of ACh, about 10^7 elementary events are required per second to maintain a depolarization of 10 mV (compare ref. 25). There would, therefore be only sufficient receptors to maintain this depolarization for 100 s if each receptor were active only once. As such a depolarization can be maintained for longer, it follows that in this case some receptors are activated more than once. With larger doses of ACh a receptor might be active only once, or a few times, before the muscle is desensitized.

Another point of interest concerns the average density of receptors at an end-plate. Consider an average end-plate in the frog sartorius, with a total synaptic length of about 600 μm (unpublished results of R. M.). Assuming a 3 μm wide contact and 1,200 synaptic folds—each with 10 μm^2 of membrane—the total synaptic membrane would then be 1.4×10^4 μm^2. If 10^9 receptors occupied only the synaptic area, there would be in the order of 10^5 receptors per μm^2. The average separation between receptor centres would then be about 3.2 nm, which would make it difficult to accommodate all the receptors in a monolayer and still leave space to accommodate the ionophores and the cholinesterase molecules known to be at the end-plate. The existence of extra-junctional receptors, however, must also be taken into account. Their distribution on the muscle fibre membrane can be estimated from the spatial pattern of ACh-sensitivity, but for the moment let us say that the synaptic area contains one-fifth of the receptors. In such a case the inter-receptor distance would still be only about 8.4 nm. But the ionophore need not be a separate molecular arrangement, since the receptor macromolecule may provide the ionic "channel"; and the cholinesterase may not be located in the membrane matrix but instead in the basement membrane, as suggested by the recent experiments of Betz and Sakmann[28].

It is interesting that, as in eel[14] and *Torpedo*[27] electric tissue, the calculated numbers of active sites of cholinesterase in frog[29], rat[30] and mouse[31] muscle fibres seem to be within an order of magnitude of the number of toxin-binding sites. This correspondence is particularly interesting because the turnover number for the enzyme is very high (about 1–10 molecules per msec per active site[29]) whereas the receptors desensitize and recover slowly.

Finally, the activity of an ACh-receptor can be predicted from preliminary estimates of the number of "effective" ACh-molecules. On collision theory, the number of collisions on a surface is $Z = nS\sqrt{\dfrac{kT}{2\pi m}}$, where n is the number of molecules per ml., S is the surface area and m the mass of the molecule[32]. During application of, say, 10^{-7} g/ml. of ACh to a sartorius muscle, and assuming that the ACh-receptor presents a target area of 20 Å^2, and disregarding hydration, there would be 3.3×10^{13} collisions/s on the receptors (i.e., 3.3×10^4 collisions/s on each receptor). If the ACh depolarized the muscle by about 10 mV, requiring 10^7 elementary events/s, then only 3×10^{-7} of the collisions are effective. This may be so, not only because many collisions have a low energy, but also because in all likelihood there are restrictions on the orientation for effective collisions. If more than one active receptor is required to elicit an elementary event, or if the target area is smaller than assumed, the number of effective collisions would be greater than estimated; all of which tends to suggest that the ACh-receptor is a rather reactive molecule.

Three computer programs applied to data from phylogenetic trees and protein polymorphism can be used to find the rate of molecular evolution of different species. It can be shown that this is slower for higher primates than for other mammals.

It is likely that the level of molecular organization in higher animals is now more complicated than would have been possible in the first life forms of three billion years or so ago. Even after the emergence of the genetic code and the biochemical apparatus of translation, natural selection would have had to act over long stretches of evolutionary time to produce the sophisticated structures and functions of the multichained proteins now found in living organisms. To begin with, almost any point mutation in a gene coding for a polypeptide chain would have been tolerable; with the evolution of higher levels of molecular organization, however, increasingly stringent functional restraints would have markedly decreased the number of acceptable mutations.

The notion that the level of molecular organization places restraints on how fast genes evolve is implicit in Ingram's hypothesis[1] that the genes for alpha globin have changed more slowly than those for beta globins. The same alpha chain combines with different types of beta chains in the several tetrameric haemoglobins which are synthesized during the life of a mammal. Since there are more restraints on variations of the alpha chains than of the beta chains, fewer mutations would be tolerated at an alpha locus than at a beta locus and alpha genes would not evolve as rapidly as beta genes. In the same way, there may be differences in the rates of evolution of the globin genes at earlier and later evolutionary stages. The original single-chained globin would no doubt have been recognizable by its three-dimensional structure and haem binding site, but it would yet have had to acquire specific sites for subunit combination, for binding diphosphoglycerate, for allosteric modulation of structure to promote the Bohr effect and for combining with the plasma protein haptoglobin. With these functions, natural selection tolerated fewer mutations in the globin genes. From this it follows that the primordial globin genes evolved more rapidly than the later globin genes of vertebrates, consonant with an earlier hypothesis that molecular evolution at a number of gene loci has decelerated, especially in the lineage leading to man[2-4].

This hypothesis, followed by others[5,6], attributes divergent evolution in proteins to selectively neutral mutations but also implies that more mutations were neutral in primitive organisms than in descendant species. Thus biochemical adaptations in human antecedents must have increased with the development of new organs such as the placenta and the cerebral neocortex and the extra functional restraints would then decrease the chances for fresh mutations to accumulate. An immunological mechanism could have further restricted the degree of genetic variability in higher primate populations, for the haemochorial placenta (with its intimate apposition of foetal and maternal blood circulations) and the long gestation period would have increased the risk to the foetus from maternal immunizations to foetal allotypes.

We present evidence in this article that molecular evolution has indeed been slower in higher primates than in other mammals. In particular, from a detailed analysis of the phylogeny of globin genes, we support Ingram's hypothesis that the evolution of alpha globin genes has been slower than that of the beta genes. Available data on proteins also bear on the cladistic relationships of man and other mammals.

The most penetrating view of the molecular changes in individual genes during the descent of man is provided by comparing the amino-acid sequences of human proteins with homologous proteins in other organisms. We have followed the approach of Fitch and Margoliash[7] in constructing gene phylogenetic trees from amino-acid sequence data and for this purpose have used three computer programs. The first program (MMUTD) calculates mutation distances for every pairwise comparison of aligned amino-acid sequences using a matrix based on the genetic code which gives for each amino-acid pair the minimum number of nucleotides that would need to be changed to bring about such a mutation. The second program[6] (UWPGM) produces from a dissimilarity matrix of the mutation distances a dendrogram of the gene species in the set. This dendrogram is an initial approximation to a cladogram, that is a graph which depicts the order of ancestral branching in the gene species set. The UWPGM builds the tree from the smallest to the largest branches in a series of pairwise clustering cycles, each time grouping together the two members of the set (either singleton species or joined species from a previous cycle) with the smallest mutation distance between them. If all the species in the set had evolved at a uniform, or nearly uniform, rate in their descent from a common ancestor, the dendrogram produced by the UWPGM would be the true cladogram[9]. But neither gene species nor animal species necessarily evolve at uniform rates. Thus, with the third computer program (DENDR) we construct alternative dendrograms. The DENDR program calculates the patristic mutation length * for each pair of adjacent nodes in a dendrogram, sums the patristic lengths through the sequence of nodes between species to calculate a reconstructed mutation distance for each pair of species in the set, and then compares the reconstructed mutation distances to the given mutation distances in the original dissimilarity matrix to calculate a coefficient for the entire dendrogram called "average percentage standard deviation" (APSD)[7]. Among the alternative dendrograms the one with least deviation between original and reconstructed mutation distances (that is, the lowest APSD coefficient) is considered the closest approximation of those tried to a true phylogenetic tree. This approach to finding the best fitting tree has proved capable of capturing the cladistic relationships among gene species even when markedly dissimilar amounts of mutational change characterize their descent from a common ancestor[10].

Globin Phylogenetic Tree

Table 1 is the matrix of mutation values from all possible pairings of sixty-eight metozoan globin chain sequences[11-47]. These chains range in size from 135 to 153 amino-acid residues. They include, apart from carp alpha, chicken alpha, and mammalian alpha and non-alpha haemoglobin chains, a globin of lamprey, myoglobins of horse and sperm whale, and a globin of the insect chironomus. The chicken alpha chain is the first non-mammalian tetrapod haemoglobin chain to be sequenced[17]. It diverges less from human (and chimpanzee) alpha than from any other mammalian alpha (Table 1). This is not due to any special relationship between chicken and man, but, as will be shown, results from the marked conservativism of higher primate alpha chains.

The best tree so far obtained depicting the phylogeny of the globins is given in Fig. 1. Fig. 2 shows the best of forty-one alternatives tried for the restricted set of tetrapod alpha chains, and Fig. 3 the best tree of forty-five alternatives tried for the restricted set of mammalian non-alpha or beta-like globin chains. The APSD coefficient was lowered from 15.11 for the alpha tree constructed by the UWPGM to 11.14 for the tree in Fig. 2, and from 11.32 for the beta-like tree by the UWPGM to 8.40 for the tree in Fig. 3. The original tree for the sixty-eight globin species constructed by the UWPGM had an APSD coefficient of 18.52. This was lowered by several points on trying a dendrogram which followed the branching order shown in Figs. 2 and 3, but which otherwise maintained the topology of the UWPGM tree. Shifting (*a*) the carp alpha branch from its UWPGM union with other alphas to a union with the line ancestral to both mammalian beta-like globins and tetrapod alphas, and (*b*) the lamprey globin branch from its UWPGM union with the branch ancestral to all the globin chains in vertebrate haemoglobins over to union with the myoglobin branch, lowered the APSD coefficient to 12.27 and produced the tree shown in Fig. 1. So far eighteen alternative configurations for the major branches of the large globin tree have been tried.

Course of Globin Evolution

The recognizable homologies between insect haem binding protein and vertebrate myoglobins and haemoglobins in codon sequence and in three-dimensional structure and functional properties[47] place the primordial globin gene deep in the Pre-Cambrian epoch before the protovertebrates had embarked on an independent course of evolution. Fig. 1 reveals that when man and lamprey still had a common ancestor, the primitive vertebrate genome already had more than one gene locus coding for globin chains; it was then that a gene duplication separated the ancestor of myoglobin genes from that of haemoglobin genes. Almost immediately after the myoglobin–haemoglobin duplication, the line leading to the globin in lamprey split off from the myoglobin side as a separate branch. Myoglobins are single chained proteins. Similarly, lamprey globins, including the one which has been sequenced, are single chained, although in certain physico-chemical conditions these lamprey globin chains form larger aggregates[45].

In the early bony fishes ancestral to the land vertebrates a haemoglobin gene duplicated to produce the split between the alpha and beta-like chain genes. This is depicted in Fig. 1 where the tetrapod alpha and beta-like lines separate from each other immediately after their separation from the carp alpha line. Much later in the lineage leading to therian mammals a gamma–beta chain gene duplicated to produce, on the one hand, the first separate ancestor of the genes for the kangaroo non-alpha chain, the human gamma chain (found in the haemoglobin of the human foetus) and the lemuroid non-alpha chains and, on the other hand, the separate ancestor for the mammalian beta chain genes. The first separate ancestor of the lemuroid (lemur and sifaka) non-alpha globin chains may have been a gamma–beta hybrid produced by unequal homologous crossing over between originally linked gamma and beta genes. There are two residues (13 Ser, 21 Glu) in kangaroo, lemur and sifaka chains and three additional residues in the lemur and sifaka chains (9 Ala, 50 Ser, 52 Ser) which are homologous to human gamma chain. Furthermore, lemur and sifaka chains resemble more human gamma from the N-terminal end than human beta and resemble more human beta from the C-terminal end than human gamma.

At the nodes of Fig. 2 for the two most ancient branching points among mammalian alpha genes, ancestral rabbit and tree shrew genes diverged from each other immediately after their separation from the branch to all other mammalian alphas. Tree shrew alpha actually shows a greater mutation distance from rabbit, and rabbit from tree shrew, than either shows from other mammalian alpha chains (Table 1). This type of pattern, which resembles that of the human gamma, kangaroo and lemuroid non-alpha branch of the beta-like tree, suggests that alpha gene duplications had occurred in the early therian mammals producing ancestral rabbit and tree shrew genes and also the ancestor of other mammalian alphas. Recent duplications of alpha genes are known to occur in present day mammals, for example, in buffalo[50], horse[27], goat[52], macaques[54], mouse[56] and probably rabbit[18].

During eutherian phylogeny, beta chain genes duplicated

---

* The patristic mutation lengths associated with any node, N, on a dendrogram are calculated as follows. Any node N divides the species of which it is the common ancestor into two sets: set A and set B. All remaining species under study comprise set C. Let D_{ab} be the average of dissimilarity values for pairs of species such that the first species is a member of set A and the second species is a member of set B, and let D_{ac} and D_{bc} be similarly calculated. The length from set A to node N is called a; the length from set B to node N is called b; and the length from set C to node N is called c. These lengths are calculated by the following formulas:

$$a=\frac{D_{ab}+D_{ac}-D_{bc}}{2}$$

$$b=\frac{D_{ab}+D_{bc}-D_{ac}}{2}$$

$$c=\frac{D_{ac}+D_{bc}-D_{ab}}{2}$$

For the special case that N is the apex of the tree (that is, the common ancestor of all species under study): $a=b=\frac{D_{ab}}{2}$

c is undefined.

independently in separate mammalian lines and certain of the descending duplicated genes ultimately coded for new proteins. For example, postnatal human blood contains in addition to its major haemoglobin (A) a minor haemoglobin (A_2) in which a different beta chain, called delta chain[1,57], combines with alpha chain. Similarly, the ceboid monkeys have a minor haemoglobin[38,58] with a beta chain (again called delta) different from the beta chain of the principal ceboid haemoglobin. Fig. 3 depicts in the early Anthropoidea, shortly after the branching apart of ceboids and catarrhine primates, two independent beta gene duplications: one on the catarrhine side coincided with the hominoid–cercopithecoid split to give rise to hominoid delta, and the other on the ceboid side produced the ancestor of ceboid deltas. Independent beta gene duplications also occurred during the evolution of the ruminants. Before the splitting apart of bovines and caprines, a descendant gene from a beta duplication in the early ruminant line began to code for the bovid foetal beta chain. The caprines (but not the bovines) have, like hominoids and ceboids, a second adult haemoglobin[45–47,59] (in this case, called haemoglobin C) normally present in negligible quantities, but synthesized in large amounts in animals under severe anaemic stress. In this second adult caprine haemoglobin, the beta C chain is found rather than the regular beta chain of caprine haemoglobin A. The ancestral *A–C* gene duplicated in the caprine line to give rise to the linked *A* and *C* gene loci shortly after the ancestral separation of bovines and caprines (Fig. 3).

Later in caprine evolution, at some point before the ancestral separation of sheep and goat, a mutation at the A locus produced the first separate ancestor of the present day sheep beta B gene. The period of separate evolution of sheep betas B and A seems to be greater than that of sheep and goat beta As. Present day sheep beta B differs from sheep or goat beta A by seven point mutations, whereas sheep beta A differs from goat beta A by four point mutations (Table 1). The sheep A and B-beta results illustrate that typical allelic proteins within a mammalian population can differ by several or more amino-acids. Bovine A and B beta alleles provide another example of such allelic variation; they differ by four point mutations

Table 1 Mutation Values from Pairwise Comparisons of Vertebrate Globin Sequences

Full name of globin species given in legend to Fig. 1. The half matrix lists minimum numbers of mutations interrelating pairs of polypeptide chains. These mutational values are converted into percentage mutational divergence

$$\left(\frac{\text{No. of mutations}}{\text{No. of shared amino-acids}} \times 100\right)$$

values, the mutation distances used for constructing the phylogenetic tree in Fig. 1. Alpha llama, sheep foetal beta, and goat A′ beta are not completely sequenced. Hence their mutation values may not represent full mutation values.

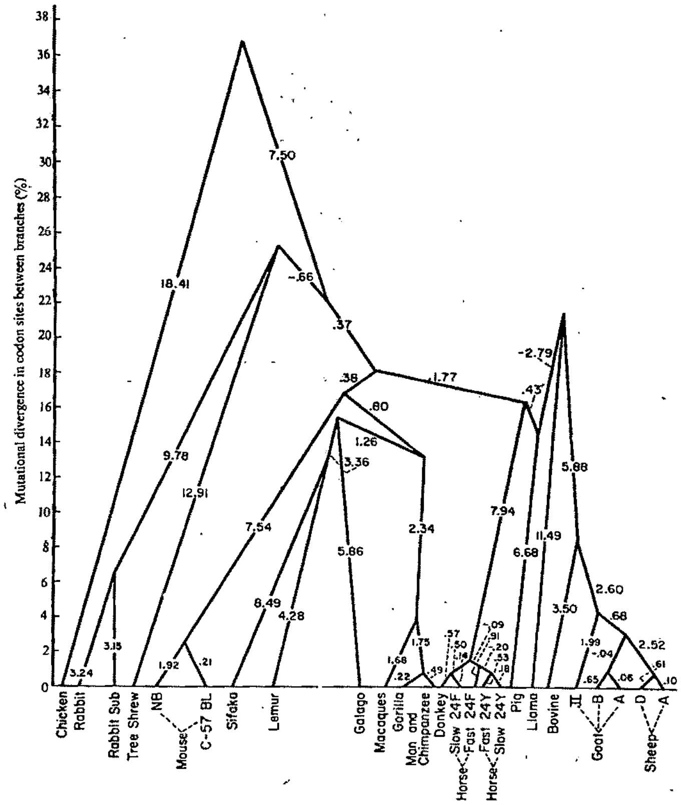

Fig. 2 Chicken and mammalian alpha globin phylogenetic tree.

(Table 1). Allelic human haemoglobins, on the other hand, differ from common human haemoglobin A mostly by only single point mutations.

The difference between bovid and human populations with respect to the kind of allelic variation expressed may be because the human foetus is at greater risk from maternal isoimmunizations than the bovid foetus. Bovids, like many mammals, have placentas of the epitheliochorial type[60] which separate the maternal and foetal vascular systems by several layers of tissue and thereby minimize the chance of maternal immune attacks on the foetus. In contrast the haemochorial placenta of the higher primates maximizes the opportunity for such attacks. Thus, the type of allelic beta chains with multiple differences in bovids, if found in man, could give rise to maternal immune reactions and be selected against. The first placentas to evolve in mammals were probably of the epitheliochorial type[60], so that the early mammals would not have been subjected to the immunological mechanism restricting genetic variability which we postulate for higher primate populations.

Rates of Globin Evolution

The patristic distance data, tabulated in Table 2, demonstrate that rates of evolution have varied markedly among vertebrate globin genes. The mammalian alpha genes diverge the least from the common vertebrate globin ancestor and the myoglobin genes; the group of non-alpha kangaroo, lemuroid, and human gamma genes diverge the most; lamprey globin, carp alpha, and chicken alpha each show more mutational change from this common ancestor than does any mammalian alpha (Fig. 1; Table 2, column 4).

While the patristic mutation lengths from Fig. 1 reveal that the proportion of codon positions showing mutations varied markedly among the principal branches of vertebrate globins, they do not show any especially marked variation among mammalian alpha genes, or among typical mammalian beta genes. But the patristic mutation lengths for the mammalian alpha portion of the globin tree from Fig. 2 and for the mammalian beta portion from Fig. 3 reveal that rates of evolution have indeed varied markedly both among mammalian alpha genes and among mammalian beta genes (Table 2, column 3). In both sets of mammalian genes, the most slowly evolving lines were those which led to man and other higher primates. In the large globin series (Fig. 1) the mutation distance between very anciently separated species, such as between any alpha and any beta globin chain, would be grossly underestimated due to uncounted multiple mutations at the same nucleotide sites. Thus, differences in rates of evolution among homologous mammalian genes, which are reflected in the patristic mutation lengths shown in Figs. 2 and 3, are smoothed out in the lengths shown in Fig. 1 where the apportioning of the mutation distances between the more recently separated genes is disproportionately affected by the mutation distance comparisons to the many, very anciently separated globin genes. Kimura[61] concluded that homologous genes evolved at uniform rates because about the same number of amino-acid substitutions separate any mammalian beta from any mammalian alpha and from carp alpha. But he failed to consider that the further in the past the separation of two lineages the larger the number of multiple mutations that must have occurred at the same nucleotide sites.

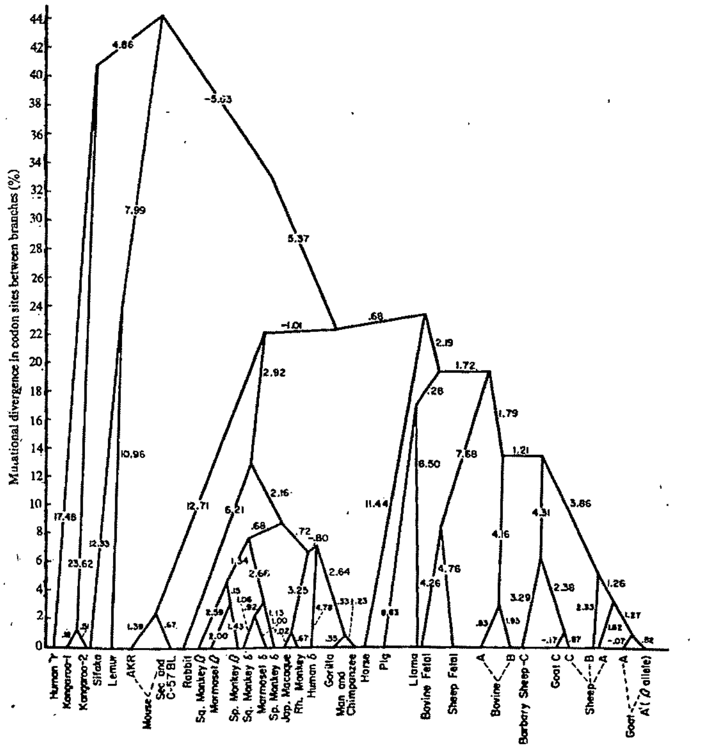

Fig. 3 Mammalian beta-like globin phylogenetic tree.

To detect a larger proportion of the accumulated mutations in a gene lineage, we constructed ancestral sequences (Table 3) for branching points of the globin phylogenetic tree and, using the MMUTD program, determined the mutation distances through the consecutive ancestors to the contemporary polypeptide chains. The mutational change in codon sites from the node for ancestral carp–tetrapod haemoglobin chains to the node for ancestral chicken–mammal alphas and from the latter to the ancestral node for mammalian alpha chains was 23.9 and 9.2% respectively. In the descent of the beta-like line, the mutational change from the ancestral carp–tetrapod node to the ancestral gamma–beta node and from this node to the ancestral node for typical mammalian beta chains was 53.2 and 2.0% respectively. The further mutational change in descent of each eutherian alpha and beta line is given in column 2 of Table 2. These results show

Table 2 Percentage Mutational Divergence of Vertebrate Globins during Descent

† Values of rabbit alpha, rabbit (sub) alpha, tree shrew alpha, mouse NB alpha and mouse C-57 alpha are directly from ancestral mammalian alpha. Values of prosimian alphas are through ancestral primate alpha node while those of catarrhine alphas are through both ancestral primate alpha node and ancestral catarrhine alpha node. Values of mouse AKR beta, mouse Sec and C-57 betas and rabbit beta are directly from ancestral mammalian beta while those of ungulate betas and primate betas are through ancestral ungulate beta node and ancestral Anthropoidea beta node, respectively.

that after the alpha–beta globin gene duplication in early vertebrate history, after the ancestral separation 380 million years ago of teleosts and tetrapods, many more mutations accumulated during the descent towards mammals in the beta-like line than in the alpha line. Moreover, during eutherian phylogeny, both alpha and beta chain evolution was much slower (on the average, almost by half) in higher primates than in other mammals. Furthermore, from the ancestral carp–tetrapod node about as much mutational change accumulated up to the ancestral chicken–mammalian alpha branching point as after this point in the descending mammalian alpha line. Yet one has to go back about 280 million years ago to the early reptiles to find the most recent common ancestor of birds and mammals. Thus the evidence suggests that the descending alpha genes evolved at a more rapid rate in earlier less advanced vertebrates than in later higher vertebrates.

The patristic distance data on beta genes show that ceboid delta, bovid foetal beta, and caprine C beta initially evolved more rapidly than the genes from which they were duplicated (Fig. 3), but later in descent their rates of evolution slowed. Note (Table 1) that ceboid deltas actually diverge less from each other than ceboid betas, that sheep and bovine foetal betas diverge less from each other than sheep and bovine adult betas, and that sheep and goat C betas diverge less than sheep and goat A betas. Presumably mutations had accumulated freely at the duplicated loci until certain fortuitous mutations resulted in the emergence of new proteins with useful functions. Then natural selection not only caused these particular advantageous mutant genes to spread rapidly through the populations in which they occurred but also drastically slowed their further evolution.

Following the gamma–beta gene duplication, more mutational change occurred in the descent of human gamma than in most typical eutherian beta chains. Nevertheless amino-acid composition data[62] indicate that slightly less divergence exists between gamma chains of man and baboon than between either beta or alpha chains of these animals. Thus when sequence data become available on gamma chains of different higher primates, the pattern of decelerating evolution will probably be found again. This pattern is presented by the myoglobin genes, for the divergence between horse and sperm whale myoglobins (Fig. 1 and Table 1) is no more than that between any two alpha chains belonging to different eutherian orders; yet the overall mutational change in the descent of the myoglobin branch is larger than in the branch containing the various chains of vertebrate haemoglobin (Table 2, column 4). Ohno[63] describes early vertebrate history as a time when tetraploidization and bursts of gene duplication were occurring in our ancestors; at the later, mammalian stage specialized functions were found for pre-existing redundant genes, but the level of genome organization was such that viable tetraploidization was no longer possible. If mutations accumulate more readily in silent genes than in functional ones, this is equivalent to the hypothesis that molecular evolution decelerated during the descent of man.

In lemurs and other prosimians, foetal haemoglobin seems to be the same as adult haemoglobin[64]. But in the lineage leading to higher primates a specialized function, coding for the non-alpha chain of foetal haemoglobin, was found for the gamma locus. A further advance took place when from certain beta duplications of the early Anthropoidea functioning delta genes and a new haemoglobin type emerged in later Ceboidea and Hominoidea. The new level of organization imposed additional functional restraints, which increased the likelihood that new mutations would be detrimental, thereby slowing the further evolution of the haemoglobin genes. While the alpha and beta chains of man are among the most slowly evolved globins, those of the kangaroo and lemuroids are among the most rapidly evolved. As previously discussed, an additional selective factor, maternal isoimmunizations to foetal antigens, might have also acted to decelerate molecular

Amino-acid residues of vertebrate globins are aligned so as to maximize homology by introducing the necessary gaps (refs. 14 and 15). The residue positions are numbered from 1 to 165 in order to accommodate lamprey globin. In this alignment carp alpha, tetrapod alphas, and mammalian betas begin at position 10 and end at position 159, with a gap at position 96. Carp alpha and tetrapod alphas have in addition gaps at position 11 and at position 62 through 66. Further gaps introduced are: tetrapod alphas at positions 57 and 78; mammalian betas at positions 29, 30, and 78; carp alpha at position 73. Residue positions omitted are the same as chicken[17] when aligned as described. Probable ancestral residues of mammalian alpha and beta chains at branching points within the span of eutherian phylogeny are given in the previous investigation[10]. Ancestral sequences were reconstructed by approximation after the rules described by Fitch and Margoliash[7]. In brief, an ancestral residue is selected if it gives fewer mutations in the lines of descent than any other residue which could be selected and, where more than one residue meets this criterion, distributes the mutations as equally as possible between the lines of descent.

evolution in the higher primates. The opportunity for such attacks would be virtually absent in kangaroo, and minimal in lemuroid primates which have epitheliochorial type placentas[65] rather than the haemochorial type of higher primates.

Cladistic Relationships of Man and Other Mammals

The phylogenetic trees constructed from amino-acid sequence data not only reveal differences in relative rates of evolution among homologous genes but also provide evidence on the cladistic relationships of the animal species in which the genes occur. The branching topologies of alpha chain genes and beta chain genes depict a very close relationship, with no detectable mutational divergence, between man and chimpanzee, and between this man–chimpanzee branch and gorilla, in which the divergence is only one point mutation per chain. A beta phylogenetic tree, which includes the partially sequenced gibbon beta chain, joins gibbon to the branch leading to chimpanzee, man, and gorilla, and then joins cercopithecoid (macaques) and hominoid branches[10]. Orang-utan haemoglobin chains have not been sequenced. Amino-acid composition data, however, show orang-utan diverging from the branch of African apes and man[66]. In the beta phylogenetic tree (Fig. 3), the ceboids branch away from the line leading to cercopithecoids and hominoids just before these two catarrhine groups branch apart. The phylogenetic tree of alpha genes (Fig. 2) joins the prosimians (galago together with the lemuroids, lemur and sifaka) to the line leading to higher primates, next joins the mouse branch to the base of the primate branch, and then joins the ancestral mouse–primate lineage with that of the ungulates. Both alpha and beta trees join caprines to bovines, llama and pig lines to the bovids, the horse branch with these artiodactyls, and then these ungulates with the lineage descending towards primates. Lemuroids do not produce a globin chain directly homologous to mammalian beta chains, so the phylogenetic tree of beta genes cannot provide cladistic evidence on the lemuroids. Otherwise the topology of the beta tree is similar to the alpha, except that rabbit beta joins primate betas before mouse.

Sequence data have also been obtained on mammalian fibrinopeptides A and B. They contain no more than forty amino-acid residues, all of which, with the exception of one or two invariant sites, have accepted amino-acid substitutions without harm to the function of fibrinogen. Thus these peptide sequences have been able to undergo such extensive divergent evolution that they are capable of depicting cladistic relationships among present day mammals. A matrix of mutation values for thirty-six mammalian combined A and B fibrinopeptide sequences[67–75] is given in Table 4, and the best tree of thirty alternatives tried portraying the phylogeny of these sequences is shown in Fig. 4. The APSD coefficient of this tree is 10.80 compared with 14.63 for the UWPGM tree.

The branching arrangement among ungulate fibrinopeptides is essentially the same as that for ungulates in the alpha and beta globin phylogenetic trees, except that more ungulate species are represented. Pronghorn and caprines join bovines and then these bovoids join cervids (reindeer and various deers). Yet caprines and cervids on the average show less mutation distance from each other than from bovines (Table 4). Doolittle and Blombäck[76] discussed the possibility that caprines might have a more recent common ancestor with cervids than with bovines, and, indeed, the tree produced in our study by the UWPGM algorithm depicts such an ancestry relationship. Nevertheless, the best arrangements of artiodactyl branches with respect to lowering the APSD coefficient placed the caprines closer to bovines than to cervids in agreement with morphological evidence on ruminant relationships.

The joining of carnivores with ungulates before they join the Primates fits established ideas on mammalian phylogeny, for the Palaeocene Condylartha and Carnivora (from which the two ungulate orders, Perissodactyla and Artiodactyla, descended) are traced to late Cretaceous palaeoryctoid insectivores[77]. The marked divergence of the rabbit line from all other mammals is also in agreement with fossil data on mammalian phylogeny[77]. Although joining rat to rabbit at the apex of the tree is not in accord with the idea[77] from palaeontological evidence that rodents evolved out of the basal Primates, it may be noted that rat fibrinopeptides show less mutational divergence from primate fibrinopeptides than from those of other mammals (Table 4). Furthermore, the globin phylogenetic trees joined mouse to the base of the Primates. A finding at variance with our general knowledge of mammalian phylogeny is the grouping of kangaroo, a marsupial, with the carnivore branch. Fibrinopeptides from additional marsupials need to be sequenced, however, if we are to construct a phylogenetic tree for the relationship between marsupial and placental fibrinopeptides.

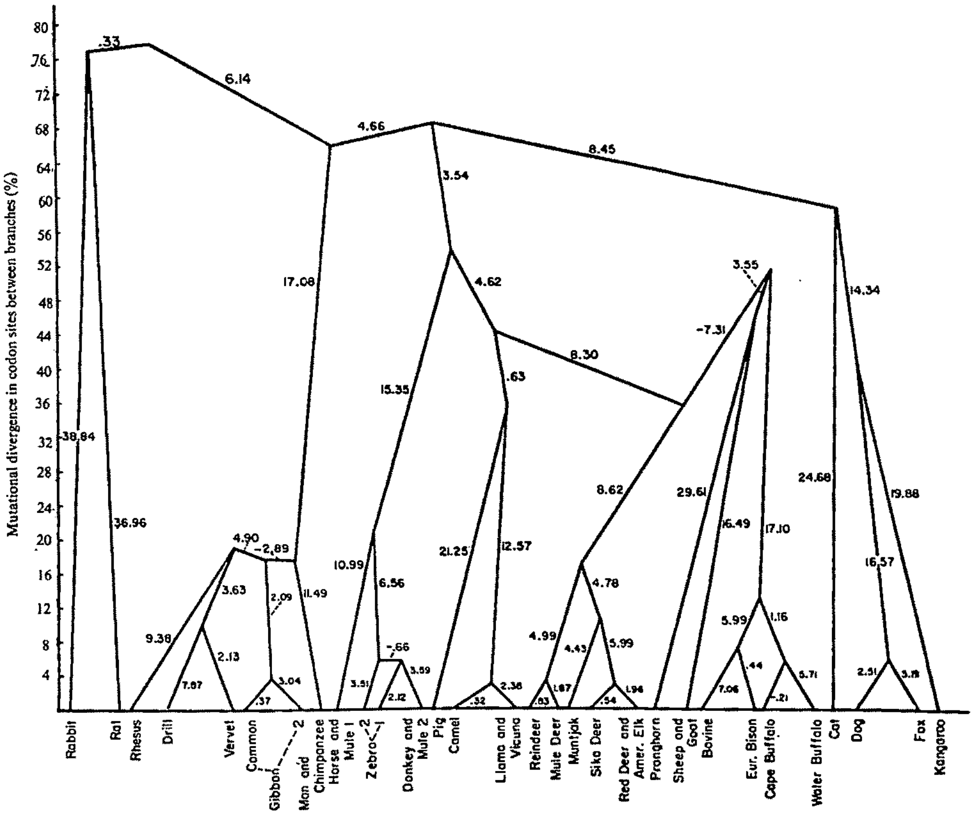

Fig. 4 Mammalian fibrinopeptide phylogenetic tree. 1, Rabbit[67,68]; 2, rat[67]; 3, *Macaca mulatta*[69]; 4, drill (*Mandrillus leucophaeus*)[70]; 5, vervet (*Cercopithecus aethiops*)[69]; 6, gibbon-1 (3 Gly–numbered from right to left)[71]; 7, gibbon-2 (3 Ser)[71]; 8, man[69]; 9, chimpanzee[72]; 10, horse[67,68]; 11, mule-1[67,68]; 12, zebra-2[73]; 13, zebra-1[73]; 14, donkey[67]; 15, mule-[67,68]; 16, pig[67,68]; 17, camel[74,75]; 18, llama[67,68]; 19, vicuna (*Vicugna vicugna*)[74,75]; 20, reindeer (*Rangifer tarandus*)[74,75]; 21, mule deer (*Odocoileus hemionus hemionus*)[74]; 22, muntjak (*Muntiacus muntjak*)[74,75]; 23, sika deer (*Cervus nippon*)[67,68]; 24, red deer (*Cervus elaphus*)[67,68]; 25, American elk (*Cervus canadensis*)[74,75]; 26, pronghorn (*Antilocapra americana*)[74,75]; 27, sheep[67,68]; 28, goat[67,68]; 29, bovine[67,68]; 30, European bison[67,68]; 31, Cape buffalo[67,68]; 32, water buffalo[67,68]; 33, cat[67,68]; 34, dog[67,68]; 35, fox[67,68]; 36, kangaroo[73].

In the descent of primate fibrinopeptides, where hominoids (chimpanzee and man) and cercopithecoids (macaque, vervet, drill) branch apart, the gibbons split off as a distinct lineage from the base of the cercopithecoids. No splitting occurs in the terminal descent of man and chimpanzee: their fibrinopeptides are identical. Furthermore, the mutational divergence among the catarrhine primates is not nearly as marked as in other comparable taxonomic groups. In this connexion, the fibrinopeptides of the catarrhine primates are among the least rapidly evolving ones in the class Mammalia as revealed by the patristic mutation lengths in Fig. 4.

In addition to the amino-acid sequence data on haemoglobin chains and fibrinopeptides, there are partial sequence data on the erythrocyte enzyme carbonic anhydrase B which can be used to depict cladistic relationships among catarrhine primates[78]. Of the 133 homologous residues examined, chimpanzee and man differ at only one site, whereas orang utan differs from chimpanzee at three sites and from man at four sites. These hominoids differ from cercopithecoids (vervet, irus and rhesus macaques, and baboon) at four to six sites. Thus again the very close genetic relationship between man and chimpanzee is highlighted. The findings from the various sets of amino-acid sequence data support the conclusion drawn from extensive comparative immunodiffusion studies[79–82] on primate proteins that in the descent of the hominoids, after the early divergence of gibbon and orang utan lines, there was still a common ancestor for man, chimpanzee, and gorilla. The cladistic relationships depicted by the protein sequences support a classification of the Hominoidea which places *Gorilla* and *Pan* with *Homo* in the family Hominidae[80–82]. This agrees with the view of Darwin[83] that man originated in Africa from the same ancestral stock as chimpanzee and gorilla.

Four to five million year old fossil remains of man's immediate generic ancestor, *Australopithecus*, have recently been found in Pliocene deposits of Ethiopia[84], and fourteen million year old remains of *Ramapithecus*[86] (*Kenyapithecus*[87]), interpreted as a lineal ancestor of *Australopithecus*, date from the terminal Miocene of Kenya. Another Kenya hominoid, an eighteen million year old *Dryopithecus* ape, is considered an ancestor of *Gorilla* and to have even then separated from the line to *Ramapithecus* and *Homo*[88]. The hypothesis that

The half matrix lists minimum numbers of mutations interrelating pairs of fibrinopeptides. Numbers of shared amino-acids vary considerably in mammalian fibrinopeptides. For example, human has thirty amino-acid residues and rhesus has twenty-five residues, all the positions of which are shared by human. The mutation value for the human–rhesus pair presented in the table is obtained from the twenty-five shared amino-acid positions. Cape buffalo has thirty-six residues, only twenty-six positions of which are shared by human. Thus the mutation value for the human–Cape buffalo pair is obtained from these twenty-six shared positions. The alignments for most of the fibrinopeptide sequences can be found in ref. 14. The mutation values are converted into % mutational divergence values for constructing the phylogenetic tree in Fig. 4.

molecular evolution decelerated in higher primates reconciles such palaeontological views with protein findings on the close genetic relationship of the African apes to man. DNA reassociation experiments[89,90] on nonrepeating polynucleotide sequences (the DNA fraction best suited for cladistic comparisons) further demonstrate the close relationship between *Pan* and *Homo*. The DNA findings emphasize the possibility that steadily increasing generation lengths may have been an important parameter[79,89,90] in slowing molecular evolution during the past sixty-five million years in the descent of man.

We thank Mr Walter Farris for assistance, Miss Joan Bechtold and Mrs Geraldine Fockler for drawings, and the staff of the Wayne State University Computing Center for help. Krypton-85 in the Troposphere

KRYPTON-85 produced by fission in nuclear reactors is at present the most abundant man-made radioisotope in the troposphere. Its activity in air was 33 d.p.m. m^{-3} air by the end of 1969 and it continues to increase. In this communication we report recent measurements of the ^{85}Kr activity in samples from air liquefaction plants at Oberhausen and Duisburg in West Germany.

The raw krypton samples were purified by removal of the oxygen in a magnesium furnace, and their activity was measured in a small gas proportional counter, of sensitive volume 11 cm^3, surrounded by a lead shield 10 cm thick; a plastic scintillator was used as an anticoincidence counter. The counting efficiency was determined from other measurements on three ^{85}Kr samples in ^{14}C and T counters whose efficiencies were known. All samples were analysed more than four months after collection and the contributions of ^{133}Xe and ^{222}Rn (half-lives of 5.65 days and 3.82 days respectively) could be neglected. The amount of Xe in the purified krypton samples (~10%) was measured mass spectrometrically and the appropriate correction made. The only other correction was that for radioactive decay since collection. The mean standard deviation of the ^{85}Kr measurement is ±2.5%.

The data are presented in Fig. 1, together with data obtained previously in our laboratory by Schölch and already published in part[1,2]. The earlier values had to be lowered by about 5 to 9% to correct a calibration error and to compensate for radioactive decay. The increase of the atmospheric ^{85}Kr activity during the past decade is apparently linear and a least squares fit of a straight line gives an average net increase of 55 d.p.m. mmol^{-1} (Kr) yr^{-1}. The actual annual production of ^{85}Kr is, of course, larger than this because of the radioactive decay. Because the total tropospheric content of ^{85}Kr and thus the loss by radioactive decay increased linearly, the actual release of ^{85}Kr activity must have increased linearly with time by $(1+t/\tau)$, from 64.5 d.p.m. mmol^{-1} (Kr) yr^{-1} in 1959 to 99.5 d.p.m. mmol (Kr) yr^{-1} in 1969. t is the time counted from late 1956 and τ is the decay time of ^{85}Kr, 15.53 yr.

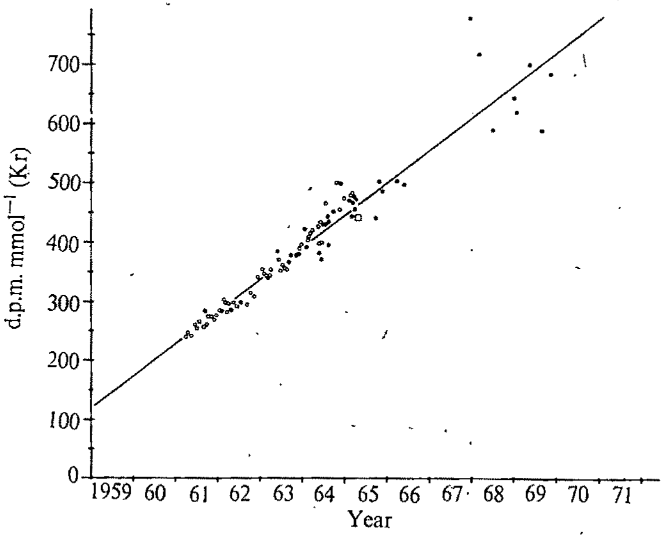

Fig. 1 ^{85}Kr activity in surface air at Duisburg and Oberhausen, Ruhr valley. ●, Recent measurements; ○, previous measurements from our laboratory; □, a sample distributed by the plant in Munich but probably collected at Oberhausen and measured by Shuping *et al.*[3]. The straight line is a least squares fit to the experimental data.

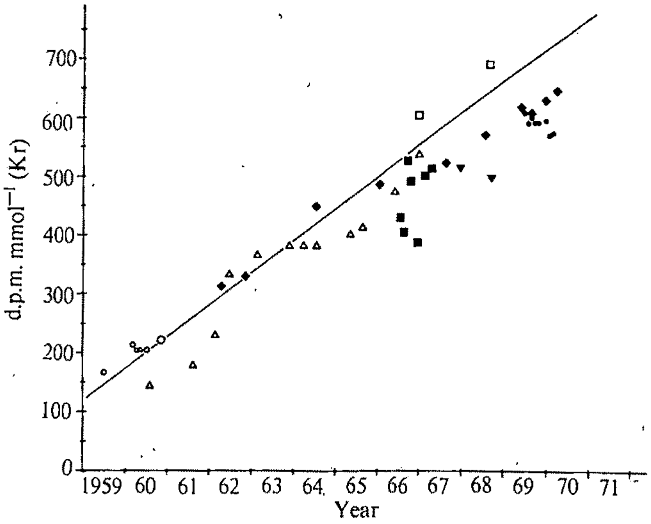

Fig. 2 ^{85}Kr activities reported at various locations by various authors. ○, Data from West Germany[7]; △, data from France[5]; □, data from Lyon, France[3]. The solid symbols represent measurements from North America[3,4]: ◆, Cleveland, Ohio; ■, Essington, Pennsylvania; ▲, Ontario; ●, Chester, West Virginia.

In Fig. 2 the ^{85}Kr measurements of other authors are compared with the fitted line. Although the individual data show a considerable scatter, even where monthly samples have been collected[2,3], the overall agreement is reasonably good and indicates that systematic differences between the various laboratories due to calibration errors are not too serious. The observed variations in the atmospheric ^{85}Kr concentration are probably real and are presumably caused by the discontinuous release of ^{85}Kr from fuel reprocessing plants and variations in horizontal and vertical mixing. A seasonal variation of the ^{85}Kr activity, which would be expected if ^{85}Kr were produced chiefly by nuclear explosions, cannot be detected above the noise level.

The data of Shuping *et al.*[3,4] from various stations of the North American continent in the years 1967 to 1969 fall below the fitted line of Fig. 2. As data from Lyon, France, measured by Shuping during the same period fall above the line, the apparent displacement cannot be explained by differences in calibration between the laboratories. In fact the average ^{85}Kr activity during 1968 and 1969 (including December 1967) was 587+9.2 for the North American stations and 668±29 for the Oberhausen and Duisburg samples, including the one sample from Lyon[3]. The mean standard deviations were calculated taking into account the systematic increase of 55 d.p.m. mmol^{-1} (Kr) yr^{-1}. The difference is 81±30, which seems significant.

The higher ^{85}Kr concentrations in the Ruhr valley could be derived from local sources. The large scatter of the samples from the Ruhr valley in 1968 and 1969, which is much larger than that of previous years (Fig. 1), also suggests contamination by local sources.

Finally the tropospheric burden of ^{85}Kr can be estimated from the present data. Using Pannetier's data[5] on meridional and height distribution of ^{85}Kr we obtain 9.65×10^{26} atoms ^{85}Kr by 1969. Assuming a linear increase of the tropospheric ^{85}Kr activity starting from zero at the end of 1956, this amount corresponds to a total ^{85}Kr production of 1.36×10^{27} atoms ^{85}Kr, which would correspond to the fission of 182 tons of ^{235}U (fission yield for thermal neutrons 0.293%, ref. 6).

The samples were provided by W. Stich of the Linde AG, Munich. The National Center for Atmospheric Research is sponsored by the National Science Foundation.

Amino-acid Synthesis from Gases detected in Interstellar Space

Fox and Windsor[1] have synthesized amino-acids by heating a solution of formaldehyde, ammonia and water to 185° C and they interpreted their results in a cosmochemical context. We now report that reaction products from different combinations of ammonia, methanol vapour, formic acid vapour and formaldehyde react to produce amino-acids when exposed to ultraviolet radiation. Because ammonia[2], methanol[3], formic acid[4] and formaldehyde[5] have been identified in interstellar space, our finding suggests that amino-acids can be formed without water in interstellar space. Also, in spite of the absence of conclusive evidence of the presence of any biomolecules indigenous to the lunar surface, our findings suggest that amino-acids can be formed on the Moon. Although the conditions of our experiments differed from those in interstellar space and on the Moon, we believe that our findings have implications for interstellar chemistry.

The combinations of gases used in our experiments were ammonia, methanol and formaldehyde, and ammonia, methanol and formic acid. The ammonia was obtained from a cylinder of the compressed gas and we generated the formaldehyde gas by heating paraformaldehyde in a flask; the methanol and formic acid vapours were formed by heating the liquids in flasks. Glass tubes led the gases from the generating flasks to a 200 ml. 'Kimax' spherical flask in which the gases reacted.

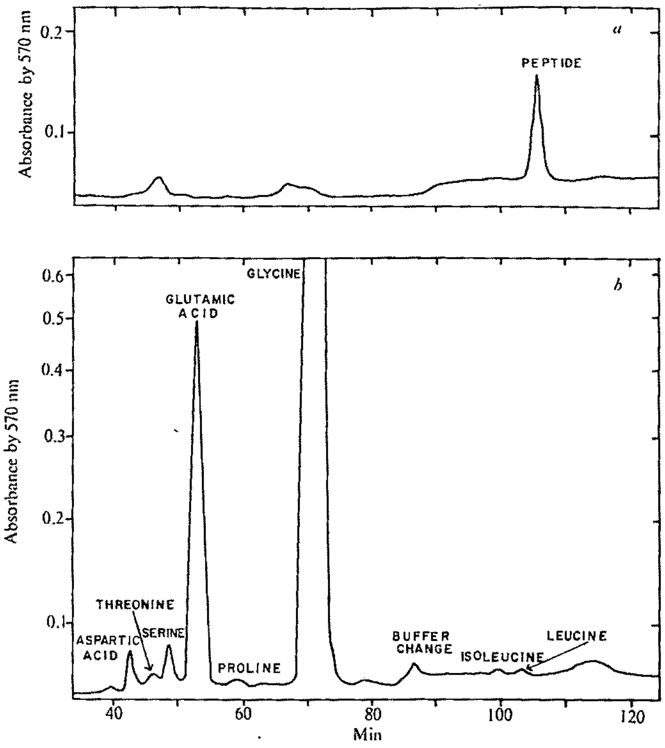

Fig. 1 Amino-acid analysis ion exchange chromatograms. *a*, Unhydrolysed, and *b*, hydrolysed samples (K) of a radiation product of ammonia, methanol vapour and formaldehyde.

All chemicals used were anhydrous because we intended to conduct the experiments without water. We also flushed out the mixing flask with ammonia before the two experimental runs to eliminate any residual water vapour. To prevent condensation of unreacted methanol and formic acid during mixing of the gases, we maintained the temperature of the mixing flask at about 115° C by directing four sunlamps on it (each 275 W) during both runs.

The gases were slowly introduced into the mixing flask and after 45 min the gas flows were stopped and the mixing flask was immediately sealed with a glass stopper.

The ammonia, methanol and formaldehyde reacted to yield 14 g of a pale yellow liquid, and the ammonia, methanol and formic acid yielded 19 g of a colourless liquid. We made no analyses of the reaction products immediately after mixing because our earlier experiments indicated that the formation of amino-acids from reaction products required exposure to ultraviolet radiation.

The flasks containing the reaction products were exposed to ultraviolet radiation from a 275 W sunlamp situated 60 cm below the flasks. The temperature at the bottom of the flasks remained at 35° C.

The liquid produced by mixing ammonia, methanol and formaldehyde started to crystallize after exposure to ultraviolet radiation for 2 days. The other reaction product started to crystallize after 7 days.

Negative tests for amino-acids indicated that the substance produced by mixing ammonia, methanol and formic acid had to be exposed to ultraviolet radiation for 25 days before amino-acids formed. The product yielded by mixing ammonia, methanol and formaldehyde was first analysed for amino-acids after exposure to ultraviolet radiation for 3 days and the analysis was positive.

The analyses for amino-acids were carried out by the method described by Moore *et al.*[6], Spackman *et al.*[7], Moore and Stein[8], and Granberg *et al.*[9]. The instrument used was a Beckman–Spinco model 120B amino-acid analyser. The samples were hydrolysed by treatment with 6 N HCl at 110° C under vacuum in sealed tubes for 24 h. Hydrolysis of the radiation reaction product of ammonia, methanol and formaldehyde yielded chiefly glycine and glutamic acid (Fig. 1). Relatively small amounts of aspartic acid, threonine, serine, proline, isoleucine and leucine were, however, also present.

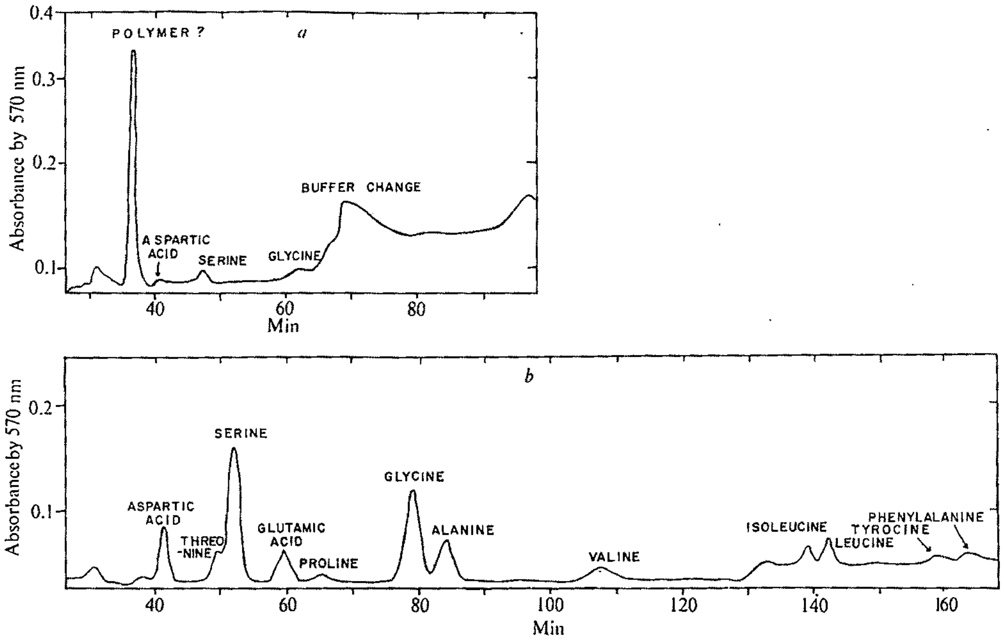

Fig. 2 Amino-acid analysis ion exchange chromatograms. *a*, Unhydrolysed, and *b*, hydrolysed samples (M) of a radiation reaction product of ammonia, methanol vapour and formic acid vapour.

The radiation reaction product of ammonia, methanol and formic acid yielded a larger number of amino-acids after hydrolysis. These included aspartic acid, threonine, serine, glutamic acid, proline, glycine, alanine, valine, isoleucine, leucine, tyrosine and phenylalanine (Fig. 2).

On hydrolysis, 50 mg of the radiation reaction product of ammonia, methanol and formaldehyde produced 0.135 mg of amino-acids—a yield of 0.27%. On the other hand, 50 mg of the radiation reaction product of ammonia, methanol and formic acid gave 0.07 mg of amino-acids—a yield of 0.14%.

The amino-acids produced by the ammonia–methanol–formic acid system are similar to those produced by Fox and Windsor[1] on heating formaldehyde, ammonia and water, and to those produced by Pavlovskaya and Pasynski[10] by ultraviolet radiation of ammonium chloride, formaldehyde and water.

The experimental procedure eliminated the possibility of accidental introduction of amino-acids as contaminants. The ammonia was provided from a cylinder of the compressed gas and thus it could not contain amino-acids—which are either non-volatile or sublime at temperatures greater than that at which the ammonia was drawn from the cylinder. By heating the paraformaldehyde, formic acid and methanol in separate flasks and introducing only the vapours into the mixing flask we avoided contamination by the non-volatile amino-acids. On the other hand, the relatively low temperature (115° C) at which the flasks were maintained precluded the introduction of those amino-acids which sublime, because they sublime at fairly high temperatures. We also tested each of the substances from which the vapours were generated; no amino-acids were found.

The chromatogram of the unhydrolysed sample (Fig. 1) indicates that ultraviolet radiation of the reaction product of ammonia, methanol and formaldehyde produced a peptide. The high peak shown in the chromatogram (Fig. 2) of the unhydrolysed sample of the other radiation reaction product indicates that a polymer might have formed. In this chromatogram as well as in the chromatogram of the hydrolysed sample shown in Fig. 1, the artefact peak due to a change in the eluting buffer is clearly marked.

A microbiuret test for peptides was positive for the radiation reaction product of ammonia, methanol and formaldehyde. The test of the other radiation reaction product was negative, suggesting that the polymer is the "HCN polymer" described by Labadie *et al.*[11], rather than polyamino-acid.

As established by mass spectrographic analyses the radiation reaction product of ammonia, methanol and formaldehyde yielded hexamethylenetetramine, but the other reaction product did not. The production of hexamethylenetetramine indicates that some water was formed during the reaction.

The facts that one of the reactions yielding amino-acids took place in the absence of water and that we only used gases suggest that perhaps some rethinking is needed about the kind of chemical reactions possible in interstellar conditions. The absence of water in our experiments strongly suggests that compounds which play an important role in the origin of life may form in interstellar space and that such compounds as amino-acids may form on the Moon.

Richard Granberg carried out the amino-acid analyses. We thank Kenneth King who suggested these experiments and M. Ewing, S. Moore, J. Oró, P. B. Hamilton, G. M. Sharma, S. J. Rasool, P. Thaddeus, D. Horn, N. T. Lui, B. Horn and B. Ericson-Moody for help. We also thank Janet Wollin for assistance. The research was supported by the US National Science Foundation.

High Precision Charged Particle Detector using Noble Liquids

WE agree wholeheartedly with P. Rice-Evans[1] and the leading article in *Nature*[2] that there is a need for higher resolution particle detectors at the new synchrotrons. Following a suggestion by one of us[3], we are working towards the development of a thin multi-conductor chamber filled with a noble liquid. Our initial efforts with liquid argon have been described in several NAL Summer Study reports[4] and the successful operation of a liquid xenon proportional counter is the subject of a recent article[5].

We shall briefly summarize what has been learned so far.

First, a liquid xenon proportional chamber with an 8 mm diameter cathode and a single 4 μm anode detects charged particles with an efficiency of nearly 100%. The pulse rises in less than 150 ns and is typically 0.15 pCi in size. (Using liquid argon, all our chambers have been sensitive only at scattered points along the wire.)

Second, the electric field necessary for electron avalanche is ∼2 MV cm^{-1}. (Consequently the central wire must be the anode in order to avoid field emission.)

Third, for the detection of ionization pulses (liquid gain = 1) produced by a movable collimated source of alpha particles, a 700 μm thick chamber with five wires spaced 25 μm apart has a spatial accuracy better than 15 μm r.m.s.

Fourth, a series of parallel conducting strips mounted on a substrate is capable of inducing electron multiplication.

Fifth, severe electronegative contamination of liquid xenon (due to unknown impurities) can occur even when the content of oxygen and nitrogen is held below 0.1 p.p.m.[6]. Many of our purification techniques are described in ref. 6.

We are now making efforts to improve our control over electronegative impurities, to show that a series of substrate mounted conductors has high precision in the avalanche mode and to develop a practical readout scheme.

Although the liquid xenon multi-conductor chamber provides accurate spatial information in its "thin" form, it also provides efficient, rapid X-ray and γ-ray detection in its "thick" form. The thin form should prove invaluable in the field of high-energy and cosmic-ray physics, and the thick form holds equally great promise in the field of radiology.

This work was done under the auspices of the US Atomic Energy Commission.

Mechanism of Oil Droplet Fragmentation in High Pressure Homogenizers

THE process of subdividing the relatively large polydisperse oil globules of a coarse oil-in-water emulsion into a large number of smaller globules of narrow size range is termed "homogenization". In a well homogenized emulsion the globules are so small that they have little tendency to rise and separate out; this is a desirable property of many emulsions of technical importance.

One of the most effective types of homogenizing machine utilizes a high pressure pump and a valve of the drop and lift type (Fig. 1*a*); pumping the coarse primary emulsion to the centre of the seating lifts the spring loaded valve and the emulsion escapes radially through the slit aperture to emerge with its oil phase finely dispersed. Machines with triple-piston pumps to minimize cyclic pressure fluctuations are used extensively in, for example, the dairy industry, for homogenizing milk, cream, ice-cream mix and other products[1]. A pressure drop of up to 250 kg cm^{-2} (3,500 pound inch^{-2}) or more may be applied across the valve and, the higher the pressure is, the smaller are the resulting oil globules. The fat globules in whole milk, which form a phase volume of about 0.035, have diameters up to about 10 μm with an average near 3.0 μm. Their subdivision into globules no larger than 1 μm may be accomplished readily with the homogenizer provided that the processing temperature is such that the fat is molten.

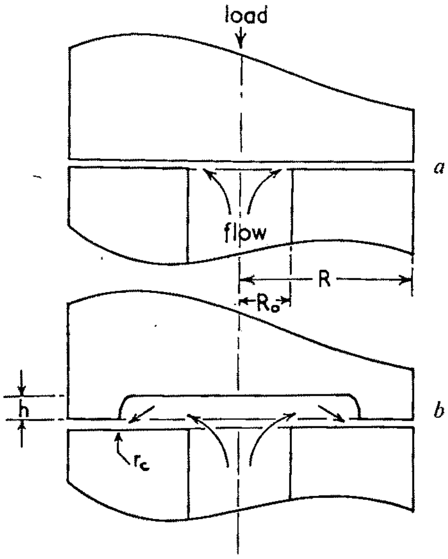

Fig. 1 *a*, Cross-section of simple flat-faced valve and seating; *b*, modified valve, to reduce the Reynolds number at r_c, the critical region for globule break-up.

In spite of the effectiveness of the high pressure machine the physical principles underlying the comminution process are obscure. I wish to report experimental data which favour one particular mechanism of droplet fragmentation. Past studies of the action of the piston homogenizer arose chiefly from the interest in homogenizing milk and my discussion is in the same context.

The lack of experimental evidence has precluded the acceptance of any one of the several theories[2] purporting to explain the physical principles underlying the homogenization of milk. Globule disruption within the valve has been variously thought to result from several effects or combinations of them. These are a shearing action within the milk itself, and between the milk and faces of the valve and its seat[3,4]; impact of the milk against the side walls of the valve[5,6]; changes in the milk velocity coupled with turbulence[7]; forces of cavitation[8–10] and, more recently, principally turbulence within the milk[11].

Some of these possibilities are questionable in the light of experimental observations. The finding that homogenization is almost complete soon after the milk enters the valve slit and before traversing the chief part of the valve radius[9] is evidence against the effectiveness of both impact forces and shearing between valve faces. Also claims that cavitational forces are responsible are not in accord with experiments which showed that effective homogenization still occurred when calculations indicated that cavitation was unlikely to be taking place in the valve[12].

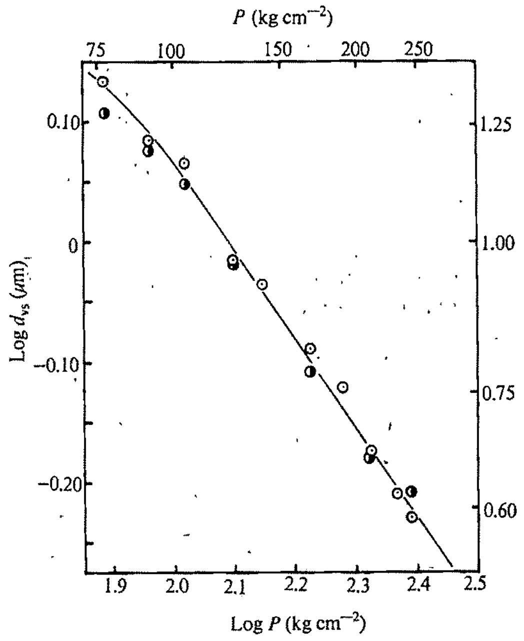

Fig. 2 The relationship between the mean fat globule diameter d_{vs} and the homogenizing pressure P at a processing temperature of 50° C. ○, Milk, normal flow rate of 100 l. h^{-1}, simple flat-faced valve (Fig. 1*a*), turbulent flow; ◑, milk/glycerol mixture, flow rate 29.9 l. h^{-1}, valve with recessed face (Fig. 1*b*), laminar flow at the critical radius for globule break-up.

The results from some of my own recent experiments support the conclusion that, in particular, shattering effects, shearing between valve faces and cavitational forces, all of which can occur to varying degree in a valve, have no significant effect on fat globule break-up. Of the remaining possibilities the effects of turbulence are of considerable interest because it has often been supposed that a turbulent flow aids homogenization. Recently, heavy turbulence has been reputed to be the principal effect involved[11] because an experimental correlation between the homogenizing pressures used and the mean globule sizes produced seemed to be explained by invoking Kolmogoroff's statistical theories of turbulence. If this were so, it would be expected that laminar flow, rather than the customary turbulent flow, through the valve would result in little or no fragmentation of globules. This has been investigated using a small capacity 3-piston machine (100 l. h^{-1}) (Rannie, Copenhagen, Denmark) in experiments with milk. A temperature of 50° C was chosen for the processing to ensure that the milk fat (melting point $\simeq 40°$ C) would be molten. The degree of homogenization or globule dispersion was assessed by turbidimetric determinations[13,14] of the mean volume–surface diameter $d_{vs}(=\Sigma nd^3/\Sigma nd^2)$ of the homogenized milk-fat globules.

Homogenizing milk at different pressures with the simple full-faced valve (Fig. 1*a*) showed that d_{vs} values, and hence the kinetics of the globule fragmentation, were reproducible. Typical results are plotted in Fig. 2*a* and show an approximately linear log/log relation[13,14]. The effect of increasing the pressure P (which produces smaller globules) and keeping the flow rate Q constant is to produce an increased emulsion velocity through the slit by a reduction in the valve lift, t. Clearly, the degree of globule dispersion is a function of this velocity. Calculations using approximate friction coefficients indicate that, for this machine, t decreases from 50 to 20 or 15 μm as P increases from roughly 10 to 300 kg cm^{-2}. The velocity at the slit entrance can be high; taking $t=20$ μm, $Q=100$ l. h^{-1}, $r=0.15$ cm, equation (1) gives $\nu=147$ m s^{-1}.

For a given flow rate Q and viscosity ν of the emulsion, the Reynolds number *Re* at any radius r of the valve face is independent of both the total pressure drop P across the valve and the width t of the slit between the valve faces. This follows from the form of the equation of continuity which, taking ν_r as the mean fluid velocity, is

$$Q=2\pi rt\nu_r \qquad (1)$$

and which combined with $Re=\nu_r t/\mathrm{v}$ gives the relation

$$Re=\frac{Q}{2\pi r\mathrm{v}} \qquad (2)$$

At the entrance to the slit, where $r=R_0=0.15$ cm for the valve in question, the *Re* defined by equation (2) is at a maximum (about 3,000) for milk at 50° C flowing at the normal rate of 100 l. h^{-1}, falling to about 800 at $R=0.55$ cm, the exit radius. The results of recent experiments (L. W. P., to be published) indicate that flow conditions would certainly be regarded as turbulent for these values of *Re*, but values of $Re \lesssim 250$ would be needed for laminar flow to be established within the valve slit.

Laminar conditions were achieved experimentally as follows. A circular recess of radius 0.4 cm was machined in the upper valve surface (Fig. 1*b*), leaving only an outer annulus of metal 0.15 cm wide to bear on the seat. The depth h of the recess was calculated to be such that the emulsion would suffer virtually no change in velocity immediately upon turning into the recess from the central conduit. This was assured by making $h=R_0/2=0.075$ cm. Radial flow of the emulsion with diminishing velocity would ensue up to the leading edge of the annular ridge, and it would then accelerate into the slit, to an extent depending on the valve lift, before finally emerging. This valve geometry produced a degree of homogenization of milk ($Q=100$ l. h^{-1}) equal to that attained at the same pressure with wholly plane surfaces. Levelling-off the annular ridge but maintaining a separation as large as h would be equivalent to operating a completely flat valve at $P\simeq 0$, and no homogenization would take place. It is certain, therefore, that globule break-up occurred at the ridge where, at the rate of flow in question, *Re* was about 1,125 ($r=0.4$ cm). A lowering of the value of *Re* at this critical radius was then achieved by reducing Q to 28.9 l. h^{-1} (that is, to about one-third of the usual rate), thus producing a transitional state of flow ($Re\simeq 320$) in the slit entrance. Such a change in conditions did not, however, impair the homogenizing effect of the valve and results were obtained for milk in close agreement with those plotted in Fig. 2.

A laminar flow at the critical radius was obtained finally by mixing glycerol with the milk to increase the bulk viscosity ν to 3.2 cS. The glycerol diluted the milk, but the degree of homogenization measured at a given pressure has been found to be insensitive to a reduction in the oil phase volume of the emulsion when this is low[14]; the presence of the glycerol was shown to have no influence on the spectroturbidimetric size analyses.

The combined effects of modifying the valve, reducing Q and increasing ν were calculated to give a value of *Re* at the entrance to the recess of approximately 270, decreasing with increasing radius to a value of 100 in the entrance to the valve slit (the critical region). In addition, the flow would be laminar in the central supply conduit and cavitation-free across the valve. The values of d_{vs} obtained at different homogenizing pressures under these conditions are plotted in Fig. 2*b*. Contrary to any expectation of poorer globule dispersion, it may be seen that values at corresponding pressures agree remarkably well with those achieved with the customary turbulent flow.

These results clearly show that turbulence does not play an important role in the fragmentation process. The possibility that two different mechanisms operate—one appropriate to laminar and one to turbulent flow—to produce identical results is hard to believe.

The degree of homogenization for a given pressure is relatively insensitive to quite large changes in Q, ν and the valve geometry; presumably this is a consequence of automatic, compensating changes in valve lift.

Experiment has shown that globules must fragment almost immediately after entering the valve slit. It has been suggested[7] that, at the slit entrance, globules are drawn into threads before they disintegrate and this seems the most likely possibility. In this region, the flow converges rapidly into the minute crevice and there is a steep velocity gradient. Such a gradient along the line of flow is to be found in a plane hyperbolic flow field and its distorting effect on globules at the slit entrance could be quite similar to the effects that have been observed in the laboratory on fluid drops in that type of field[15,17]. In those experiments, deformation and extension of a drop in the flow direction occurred; at a sufficiently high shear rate—depending on the fluid system—the drop could be drawn into a cylindrical thread which subsequently disintegrates into several small drops, particularly if the generating flow was abruptly retarded or stopped. In this type of flow threads can be formed even if the ratio of the viscosity of the emulsified drop to that of the suspending medium, η_1/η_0, is as high as 20 (ref. 15) or, as we have found by experiment, even 50 or more. The high value of 26 in the case of milk would, therefore, seem unlikely to impose any restrictions on the disintegration of molten milk fat globules by this mechanism. By contrast, it seems that in simple laminar shear flow drops do not disintegrate when $\eta_1/\eta_0 > 4$ but merely distort and twist in the flow[16]. It follows that, in the experiment above with laminar flow of the milk/glycerol mixture, the fact that η_1/η_0 was 6.4 is incompatible with a simple shear mechanism of break-up; this accords with experiment.

Calculations[17] of the minimum shear rate or velocity gradient G needed to deform a milk fat globule in hyperbolic flow give some idea of the local gradient that would be necessary to do this at the entrance to the valve slit. Thus taking an average globule diameter of 3 μm, a viscosity of 0.01 P for the continuous phase and 5 dyne cm^{-1} for the interfacial tension[18], a value of $2.5 \times 10^6\ \text{s}^{-1}$ is found. For a fairly high pressure drop across the valve the average velocity at the entrance to the slit can be $\sim 10^4\ \text{cm s}^{-1}$; the small upstream approach velocity may be neglected in comparison. Gradients of $G \sim 10^6\ \text{s}^{-1}$ would be possible, therefore, provided that the velocity change occurred over distances of the order of 10^{-2} cm. The rapidly decelerating radial flow of the bulk emulsion across the valve, which succeeds its acceleration into the slit, would then appear to be an appropriate condition for disintegration of the thread-like particles.

The degree of elongation and break-up of a globule probably depends on its precise trajectory into the slit because the velocity gradient across the width of the slit at the entrance would produce a corresponding variation in G over the cross-section. The greatest rupturing effect would be expected in the centre of the stream where the velocity is greatest and G is a maximum, though the length of the disrupting zone may still not favour the greatest break-up effect possible. Thus a single passage of the emulsion through the valve could not produce the maximum dispersive effect; this accords with the fact that repeated homogenization of the same emulsion at constant pressure progressively increases globule dispersion.

Speculating on the somewhat improved dispersion that can be achieved with breaker rings[4] and corrugated valve surfaces[7,19], it seems likely that this arises from the introduction, by these modifications, of additional regions where accelerated flow can occur.

I thank Professor J. N. Hunt, Applied Mathematics Department, University of Reading, for his interest and Miss S. Higgs and Mrs V. Bines for technical assistance.

BIOLOGICAL SCIENCES

New Type of Compound with Strong Sweetness

CHEMISTS have long been interested in sweet substances to be used in place of sugar for medical and dietary purposes, and several such substances have been found in natural sources or as synthetic compounds. Sodium saccharin, sodium cyclohexylsulphamate, glycyrrhizin[1] (V), stevioside[2] (VI), naringin dihydrochalcone[3] (VII), neohesperidine dihydrochalcone[3] (VIII), and L-aspartyl-L-phenylalanine methyl ester[4] (IX) are well known as sweeteners, some of which have been put to practical use. We wish to report a new type of sweet compound with a different structure.

Studies on chemical conversion of pine tree rosin to biogenetically active compounds have been carried out in our laboratory. Recently four stereoisomers (I, II, III, and IV) of 4β, 10α-dimethyl-1, 2, 3, 4, 5, 10-hexahydrofluorene-4α, 6-

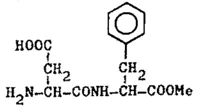
(VII) R=

(VIII) R=



(IX)

dicarboxylic acid have been synthesized from pine tree rosin[5], one of them (I) had a remarkably sweet taste although the others had no taste. The taste of this compound had some bitterness besides the sweetness (Table 1). It is unique in that its structure is that of a simple diterpenoid. Though glycyrrhizin (V) and stevioside (VI) have a similar terpenoid skeleton, they have a glycoside formula as a whole. Correlations between sweetness and structure have been sought by many researchers, and the fact that only one out of four stereoisomers had a sweet taste should make a significant contribution. We are now working on its large scale preparation and on toxicity tests (acute, subacute, and chronic).

Table 1 Comparison of Taste

Compound	Relative sweetness (threshold value for sweetness; conc. % in H_2O solution)
Sucrose[6]	1
(Ia)	1,300~1,800 (0.0006%)
Na salt of I (Ib)	1,600~2,000 (0.0007%)
Sodium saccharin[6]	200~700
Sodium cyclohexylsulphamate[6]	30~ 80
Glycyrrhizin[6] (V)	50
Stevioside[6] (VI)	300
Naringin dihydrochalcone[6] (VII)	300
Neohesperidine dihydrochalcone[6] (VIII)	2,000
L-Aspartyl-L-phenylalanine methyl ester[6] (IX)	100~200
Compound	**Relative bitterness**
Caffein	1
(Ia)	12~18
Na salt of I (Ib)	12~13

Lesions due to Complement in Lipid Membranes

WHEN cells are lysed by antibody and complement (C), uniform bubbles or "holes" revealed by negative staining in the electron microscope appear at the surface. These lesions are probably due to micelle formation in the surface lipid layer (evidence reviewed in ref. 1). C activated by antibody through C8 has also been shown to damage liposomes containing Forssman antigen in their lipid membranes[2,3], though not to make holes in them[4]. C activated in the "reactive lysis" system (involving attachment to erythrocyte membranes or other hydrophobic surfaces of an unstable $\overline{\text{C567}}$ complex which in turn interacts with C8 and C9[5]) causes typical lesions in erythrocyte membranes[6] and in lecithin liposomes[7].

Although the detailed mechanism remains to be elucidated, the evidence indicates that the terminal components of C act on a lipid substrate to form micelles and that this is responsible

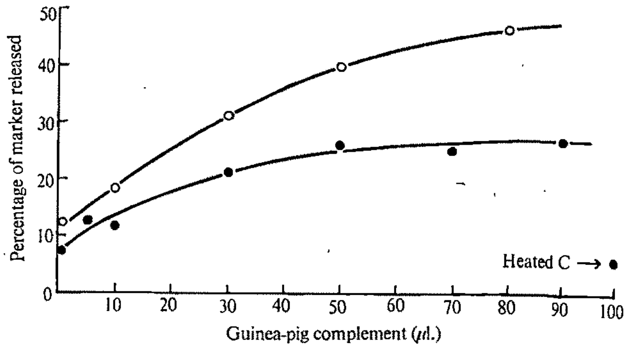

Fig. 1 Release of glucose marker from liposomes (made from extracted sheep erythrocyte lipids), as a function of the amount of guinea-pig C added. 200 µl. total reaction mixture was incubated for 1 h at 37° C. Anti-Forssman antibody dilution 1 : 10, ○; 1 : 25, ●.

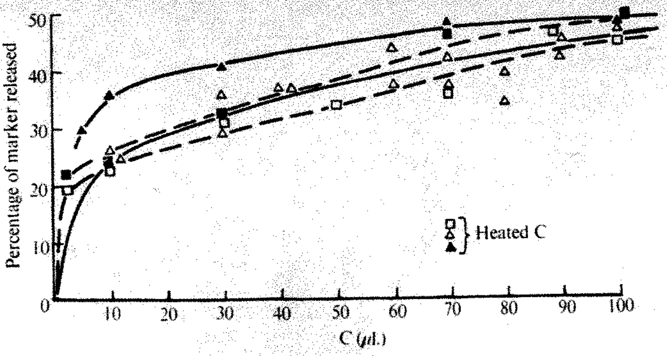

Fig. 2 Glucose marker release with human and rabbit C. Incubation conditions were as in Fig. 1. □, Human C; ■, human C+1 : 25 antibody; △, rabbit C; ▲, rabbit C+1 : 25 antibody.

for the irreversible cell damage. The only contrary evidence is a report that holes are formed by the action of C5, before cell damage is apparent[8], and the failure to demonstrate holes in liposomes damaged by C activated by antigen-antibody combination. We wish to report that typical holes are formed when liposomes are damaged by C in both the conventional antibody-mediated and the reactive lysis systems but that no lesions are detectable when C6-deficient rabbit serum is used as the source of C.

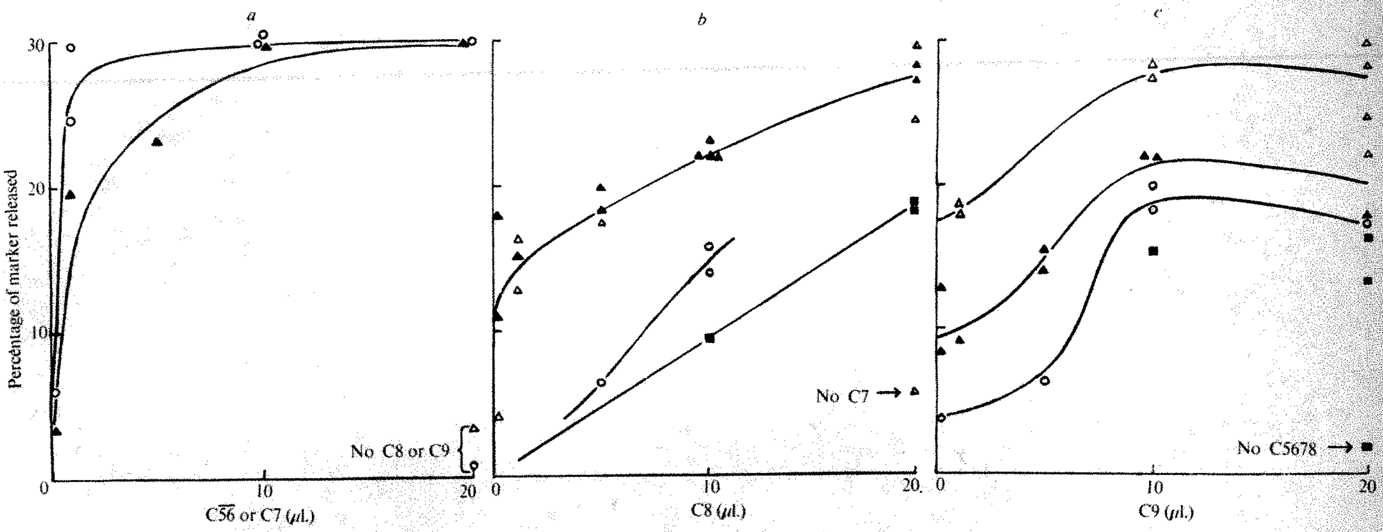

Fig. 3 Marker release from liposomes in the reactive lysis system. Conditions as for Fig. 1. *a*, ▲, 20 μl. C8+20 μl. C9+10 μl. C7+variable C$\overline{56}$; ○, 20 μl. C8+20 μl. C9+10 μl. C$\overline{56}$+variable C7. *b*, △, 10 μl. C$\overline{56}$+1 μl. C7+variable C8+ :−20 μl. C9; ▲, 10 μl. C9; ○, 5 μl. C9; ■, 1 μl. C9. *c*, △, 10 μl. C$\overline{56}$+1 μl. C7+variable C9 + :−20 μl. C8; ▲, 10 μl. C8; ○, 5 μl. C8 ; ■, 1 μl. C8.

Liposomes (aqueous dispersions of vesicles with walls of one or more stable bimolecular lipid layers containing Forssman antigen) were prepared from the lipid mixture extracted from sheep erythrocyte membranes (or whole washed erythrocytes) with 2 : 1 chloroform : methanol, and evaporated to dryness under a stream of dry nitrogen.

Samples of some preparations were dissolved in diethyl ether and added to 0.3 M aqueous glucose, and the ether was removed by evacuation in a rotary evaporator for about 30 min. In other samples dried lipids were allowed to swell in 0.3 M glucose under nitrogen without agitation for at least 2 h. Both methods yielded turbid suspensions containing 5–15 μmol total lipid per ml. based on the mean composition for sheep erythrocyte lipids[9]. After standing overnight liposomes were separated from most untrapped glucose by passage through a column (1.8 × 50 cm) of 'Sephadex G-25' (coarse), using for elution either the barbitone buffer (*p*H 7.2) (referred to hereafter as VBS) containing optimal amounts of Mg and Ca described by Mayer[10], or a lower ionic strength buffer (0.06 M NaCl, 0.18 M lactose, 4.87 mM Na barbitone, 1 mM $MgCl_2$, 0.15 mM $CaCl_2$ adjusted to *p*H 7.2). Preparations were stable for at least 3 weeks when stored under N_2 at 3° C. The presence and availability of Forssman antigen ware checked by showing that 1 ml. of the liposome preparation would neutralize about 97% of the haemolytic activity in an equal volume of a rabbit anti-Forssman antibody containing 200,000 haemolytic units per ml.

Release of glucose marker was measured by the change in absorbance at 340 nm due to reduction of TPN in the presence of hexokinase, glucose-6-phosphate dehydrogenase and ATP[11]. Both C and antiserum were dialysed beforehand in the cold against the appropriate buffer to remove pre-existing glucose, and a correction was made for any remaining traces. In most experiments 100 μl. of liposome suspension was mixed with diluted rabbit antibody followed by varying amounts of human, guinea-pig or rabbit serum as a source of C, and the volume was made up to 200 μl. with VBS. A suspension of liposomes in buffer was included as a control for untrapped glucose. After 1 h at 37° C the glucose released was measured, and the total glucose present was determined after complete lysis of the liposomes by adding 'Triton X-100' in chloroform at a final concentration of 2%. Release of glucose did not exceed about 5% with Forssman antibody over a range of concentrations 10^{-2} to 10^{-5} with or without heated C (56° C for 60 min) up to a concentration of 1 : 2.5. With antibody and active C, however, as much as 50% of the glucose was released (the amount varied with different liposome preparations, but was reproducible with a given preparation). Fig. 1 shows that the release by different amounts of guinea-pig C in the presence of 1 : 10 or 1 : 25 dilutions of antiserum (approximately 200,000 haemolytic U/ml.) reached plateau values of about 45 and 25% at 1 : 2.5 and 1 : 4 concentrations of C respectively. Fig. 2 shows similar curves for human and normal rabbit C (both of which contained "natural" Forssman antibody), with and without 1 : 25 added rabbit antibody. The lowest concentration of human C tested (1 : 100) caused about half maximal release

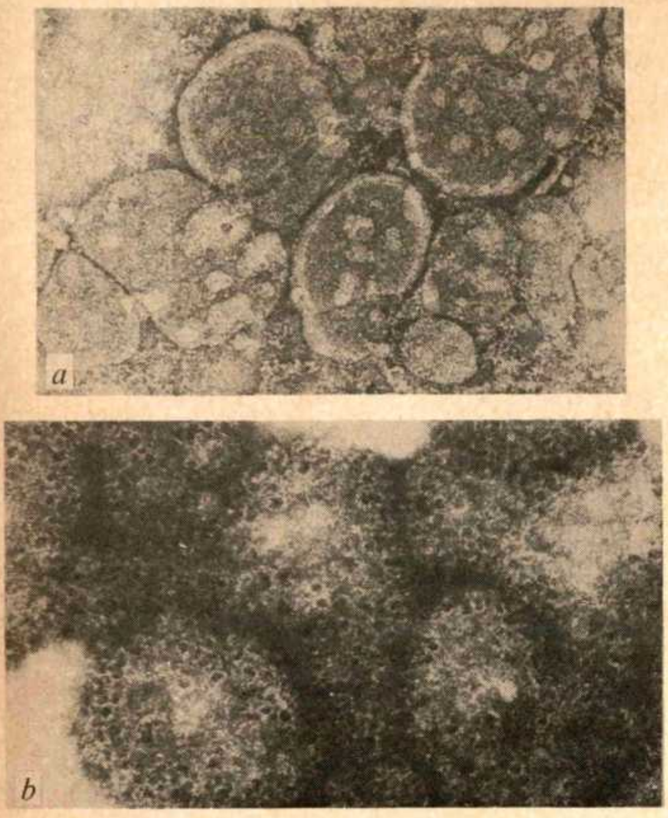

Fig. 4 Electron micrographs (negative staining) of grids coated with liposomes, treated with Forssman antibody and incubated (*a*) with heat-inactivated human C; (*b*) with unheated human C (× 120,000).

of glucose, even without additional rabbit antibody, and 1 : 40 rabbit C with added antibody released even more.

When C6 deficient rabbit serum[12] was tested as the source of C for the same range of concentrations no glucose was released in excess of the heated C control. That the C6 deficient serum was not inhibitory was checked by showing that addition of 1 : 10 normal rabbit C produced the expected degree of release even in the presence of three times as much C6 deficient serum.

The effect of different components of the reactive lysis system on liposomes was studied using human reagents prepared as described before[5,6]. 100 μl. of liposome suspension was stirred for 2 min at room temperature with a preparation of C$\overline{56}$; purified C7 was next added and stirring was continued for 5 min at 37° C. Purified C8 and C9 were added last and the mixture was stirred and incubated at 37° C for 1 h. Fig. 3*a* shows the effect of varying C$\overline{56}$ or C7 in the presence of an excess of the other reagents; glucose release increased as more C$\overline{56}$ was added up to 1/10 of the total volume, whereas maximal release occurred with minimal amounts of C7. When the concentration of C$\overline{567}$ was constant and the concentrations of C8 and C9 were varied, glucose release was maximal at about 1/10 C9 (Fig. 1*b*) and 1/10 C8 (Fig. 1*c*). Considerable release occurred at the highest concentrations of C8 in the absence of added C9, but the inference that C9 is unnecessary for lysis is weakened by uncertainty whether the C8 preparation was completely free of C9. Marker release in the presence of C$\overline{56}$, C7, C8 and C9 was increased by up to 7% by 0.01 M EDTA. In the absence of any single component, other than C9, it was minimal.

Attempts to demonstrate typical C lesions on liposomes by negative staining in either system were unsuccessful when carbon coated electron microscope grids were floated on or dipped into the liposome preparation at the end of the incubation period, when damage was expected. Even when the final suspension was prefixed by adding osmium tetroxide, damaged liposomes were not seen. Since it was possible that damaged liposomes might not attach to the grids, we tried allowing the liposomes to adsorb to the grids before damage occurred. Grids coated with 'Parlodion' and carbon were floated at room temperature on the original liposome suspension when using the Forssman antibody system, or on liposomes treated with C$\overline{56}$ and C7 for the reactive lysis system. After 10 min the grids with liposomes attached were rinsed in VBS and floated on diluted antibody followed by C or on C8 plus C9 respectively, and incubated at 37° C for 1 h. After incubation grids were washed in VBS (*p*H 7.2), negatively stained with 2% sodium silicotungstate and dried. Electron micrographs of grids coated with liposomes in this way, and then treated with IgM antibody and heated human C, showed liposome spherules about 0.1 to 1 μm in diameter covered with small filamentous particles which might be molecules of IgM. The appearance of grids coated similarly with liposomes, but treated with

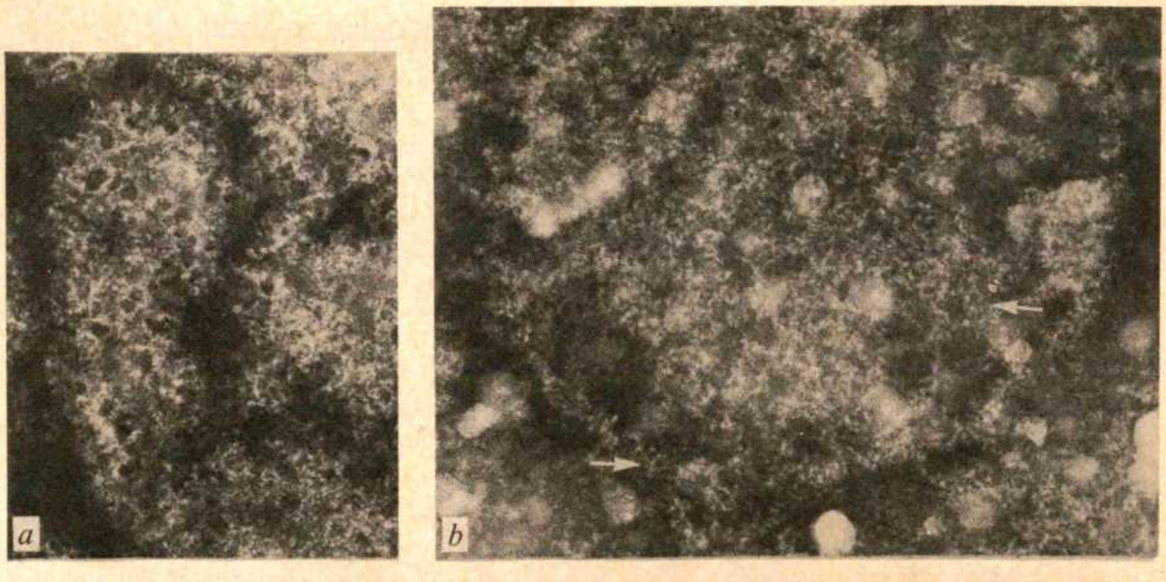

Fig. 5 Liposomes prepared as in Fig. 4, treated with Forssman antibody and *a*, normal rabbit C; *b*, C6 deficient rabbit C. Arrows point to ring-like structures (× 192,000).

antibody and unheated human C, differed in that most liposomes had either disappeared or were less prominent, and that both the remaining liposomes and the surrounding surface were covered with typical C holes (Fig. 4). These had a central dark area about 10 nm in diameter, similar to those produced by human C on *E. coli* lipopolysaccharide[1], though the external ring seemed to be narrower. Grids treated with antibody and normal rabbit C had similar holes. With C6 deficient serum "holes" were not evident, but some smaller ring-like structures could be discerned which may correspond to the membrane alterations reported after the action of C1-5[8] (Fig. 5). Typical lesions were obtained with the complete reactive lysis system, but when C8 and C9 or pretreatment with $\overline{C567}$ were omitted none were detected.

These experiments confirm evidence[1] that C-mediated damage to membranes, sufficient to cause them to leak, is correlated with disruption of the membranes by formation of characteristic micellar structures, visualized as holes within them. It is probable that holes were only visualized regularly when liposomes were adsorbed on the grids before disruption because the constituents of the liposomes, which are quite fluid structures, reassemble into smaller fragments when liposomes are disrupted in suspension. No lesions were apparent before the addition of C8 and C9 in the reactive lysis system, nor with C6 deficient serum in the conventional system; therefore the lesions must presumably be the final cause of damage and not incidental byproducts. Since the liposomes were composed only of lipids, the substrate upon which the terminal components of C act is presumably lipid, although it has not been formally excluded that some surface active substance, for example, a peculiar peptide, might be formed from one of the later C components and inserted into the lipid membrane. The report of Lachmann *et al.*[7] that holes could be produced by the reactive lysis system on pure lecithin liposomes indicates that the substrate is likely to be phospholipid, especially since lipid analysis revealed only a trace of cholesterol in any of the reagents which they used. The extent of any chemical changes may be very small, however, because none have yet been detected either by Inoue and Kinsky[13] who studied the action of guinea-pig C on liposomes containing Forssman antigen, or by one of us (S. N. P., unpublished) in a system involving human C and *E. coli* cell walls.

Luminescent System in a Myctophid Fish, *Diaphus elucens* Brauer

The myctophids, or lantern fishes, which migrate diurnally to the surface at dusk, are among the most common and widely distributed deep-sea fishes known. They emit a blue light from tiny dermal photophores[1] arranged in species-specific patterns over the ventral and lateral surfaces of the body. Certain species also possess a large nasal or caudal organ. Although hydrogen peroxide stimulates the photophores to luminesce[2], nothing is known about the molecular mechanism involved. We report that photophore extracts of the myctophid, *Diaphus elucens* Brauer, cross-react to give light with highly purified luciferin (substrate) and luciferase (enzyme) of the marine ostracod crustacean, *Cypridina hilgendorfii*. The *Cypridina* luminescence reaction is due to the oxidation of luciferin by molecular oxygen, catalysed by luciferase.

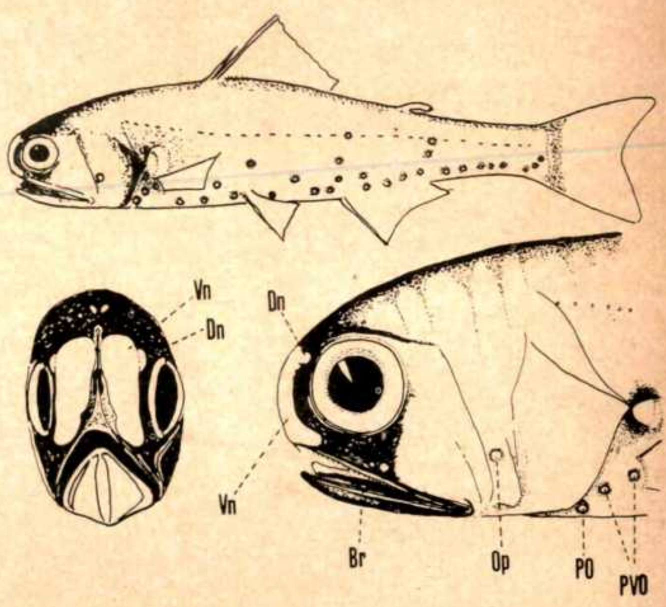

Fig. 1 *Diaphus elucens*, showing luminous organs on trunk and head. Note the large ventro-nasal organ (Vn) and the dorso-nasal organ (Dn). Other luminous organs: branchiostegal (Br), opercular (Op), pectoral (PO), and subpectoral (PVO). Drawn from actual specimen. Terminology of the photophores is according to Bolin[3].

Specimens of *D. elucens* were netted at night off Yui, Suruga Bay, Japan, at depths of 20–30 m as they migrated toward the surface from areas of the Bay, 1,000–1,600 m deep. They were preserved at −35° C. Specimens were 102–140 mm long from tip of snout to tail base and 24–31 mm deep. The distribution of the luminous organs is shown in Fig. 1. Cell-free extracts were prepared by grinding 100 dermal photophores in 10 ml. of 0.05 M Tris (pH 8.0) in a glass homogenizer chilled in an ice bath. The homogenate was centrifuged at 12,500g for 10 min at 4° C. The extract was dialysed overnight at 4° C against distilled water. *Cypridina* luciferin (in 0.1 N HCl and stored under argon in an ice bath to prevent autoxidation) and luciferase (1.73×10^{-6} mg/ml., in water) were prepared as previously described[4,5]. Light intensities were measured in arbitrary light units with a MacNichol photomultiplier (RCA 1P21) photometer[6].

Fig. 2 shows the result of mixing a highly active *Diaphus* extract with *Cypridina* luciferin. The light intensities (directly proportional to reaction rates) are plotted against time according to the equation for a first order reaction. The rate constants were for curve *a*, 4.59×10^{-2} s^{-1}; curve *b*, 2.15×10^{-2} s^{-1}; and curve *c*, 1.99×10^{-2} s^{-1}. They are very nearly proportional to extract concentration (curves *a*, *b*) and independent of luciferin concentration (curves *b*, *c*). The luminescent reaction therefore is first order and resembles the *Cypridina* reaction[4]. The reason for the high initial rate is unknown, but it also occurs in the *Cypridina* reaction[4].

The emission spectra of the reaction between *Diaphus* extract and *Cypridina* luciferin, and between *Cypridina* luciferin and luciferase, were measured with an Aminco-Bowman spectrophotofluorometer, using a Moseley 7035A (Hewlett-Packard) X-Y recorder. The *Diaphus* extract and *Cypridina* luciferase (+0.7 ml. 0.2 M Tris (*p*H 8.0)) were each injected into *Cypridina* luciferin diluted with 2 ml. of 0.2 M Tris (*p*H 8.0). The spectra are virtually identical (Fig. 3) and run from about 400 nm to about 600 nm, with a maximum at around 456 nm and half-intensity width of about 70 nm.

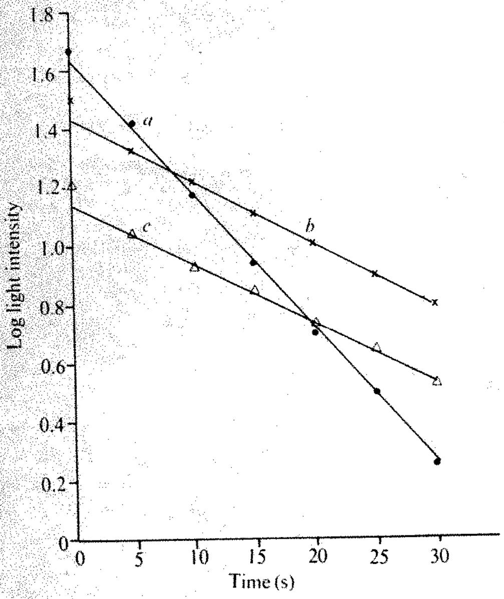

Fig. 2 Luminescence decay curves obtained by injecting *Diaphus* photophore extract into buffered *Cypridina* luciferin. Curve *a*, 1 ml. extract, 0.2 ml. luciferin, 2 ml. of 0.2 M Tris (*p*H 8.0); curve *b*, 0.5 ml. extract, 0.2 ml. luciferin, 2.5 ml. of 0.2 M Tris (*p*H 8.0); and curve *c*, 0.5 ml. extract, 0.1 ml. luciferin, 2.6 ml. of 0.2 M Tris (*p*H 8.0).

Diaphus extract mixed with *Cypridina* luciferin in anaerobic conditions did not luminesce until air was admitted. The activity of the extract was inhibited by immunoglobulin G isolated from rabbit antisera against *Cypridina* luciferase[7]. The inhibition of *Cypridina* luciferase by specific antisera but not by normal sera[8] indicates that the extract contains an enzyme similar to *Cypridina* luciferase. *Diaphus* extract (undialysed) also gave light with *Cypridina* luciferase. Only a slight stimulation of light emission occurred when *Diaphus* extract was mixed with 0.5% H_2O_2 or 0.5% H_2O_2 with either crystalline beef liver catalase (Worthington, 1 mg/ml., in water) or horseradish peroxidase (Worthington, 0.5 mg/ml., in water). *Cypridina* luciferin mixed with 0.5% H_2O_2 produced a brighter light. Nasal organ (Fig. 1, Vn, Dn) extracts gave results similar to dermal photophore extracts. Light was emitted when muscle and stomach extracts were mixed with *Cypridina* luciferin and luciferase. Purified luciferin and luciferase (details of which will be reported elsewhere) of the deep-sea decapod shrimp, *Hoplophorus gracilorostris*, also produced light with *Diaphus* extracts and *Cypridina* luciferin and luciferase.

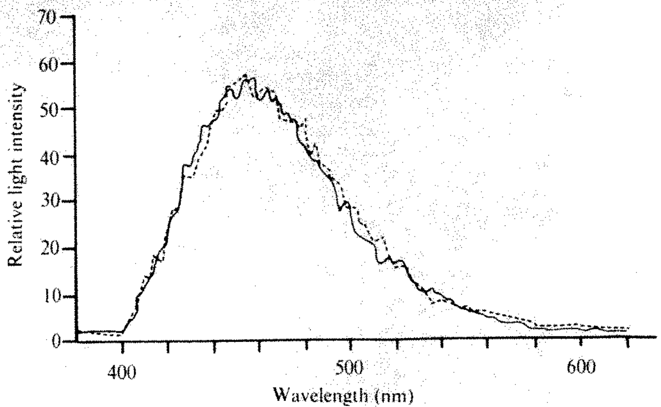

Fig. 3 Emission spectra of *Diaphus* extract–*Cypridina* luciferin and *Cypridina* luciferin–luciferase reactions. *Diaphus* spectrum (——): 1 ml. dialysed *Diaphus* extract, 0.2 ml. *Cypridina* luciferin, 2 ml. of 0.2 M Tris (*p*H 8.0). *Cypridina* spectrum (- - -): 0.3 ml. of *Cypridina* luciferase (1.73×10^{-6} mg/ml., in water), 0.2 ml. *Cypridina* luciferin, 2.7 ml. of 0.2 M Tris (*p*H 8.0). The monochromator was calibrated with a mercury light source but the curves are not corrected for either photomultiplier (RCA 1P21) sensitivity or luminescence decay.

Results with *Diaphus* extracts have been confirmed with extracts of the dermal photophores and infracaudal organ of another myctophid, *Stenobrachius leucopsarus*, collected off the coast of southern California. Cell-free extracts of the ventral photophores of the hatchet fish, *Polyipnus spinosus*, from Suruga Bay, and *Sternoptyx diaphana*, from southern California, also cross-reacted with the *Cypridina* system and showed properties similar to the myctophid system. We conclude that in *D. elucens*, and the other species studied, the biochemical mechanism for luminescence involves a luciferin and luciferase similar to the luciferin and luciferase of *Cypridina*.

We thank Dr B. G. Nafpaktitis and Mr W. T. O'Day for collecting *S. leucopsarus* and *S. diaphana* and Dr T. Abe for identifying *D. elucens*. The study was supported by grants from NSF and the Japan Society for the Promotion of Science under the US–Japan Cooperative Science Program.

BOOK REVIEWS

Weakness at Reading

Reading and its Difficulties: a Psychological Study. By M. D. Vernon. Pp. viii+211. (Cambridge University: London, September 1971.) £3.20; $10.50.

THIS book is a sequel to Professor Vernon's *Backwardness in Reading,* published in 1957, and it deals for the most part with research which has been carried out since that date. A wide variety of experiments are cited: on visual perception, on auditory and linguistic development in children, on the relation of reading to intelligence, and on the social and motivational factors which are associated with high and low scores on reading tests. Finally, Professor Vernon examines some of the evidence relating to specific dyslexia (a disability, or group of disabilities, in which weakness at reading is accompanied by directional confusion, difficulty in spatial and temporal sequencing and very strange spelling mistakes).

As usual, Professor Vernon's standards of thoroughness and scholarship are admirable. The evidence on perception of form and print is particularly well presented; and above all I should like to pay tribute to the chapter on dyslexia, which I wish could be made compulsory reading for everybody concerned with educational planning.

I have one chief criticism. In parts of the book, particularly in the chapters on the relevance to reading of intelligence and of social and motivational factors, Professor Vernon seems to me to have been too charitable to research of dubious merit. Occasionally, it is true, she refers to inadequacies of experimental design or suggests that an author's interpretation of his findings may be questionable. It may well be, however, that educational research, if it is to prosper, requires not mere improvement here and there but radical re-thinking. Countless man-hours have been spent on "measuring" such allegedly useful entities as "IQ" and "reading age", on making judgments about parental support or children's degree of application (sometimes, incidentally, value-laden and arrogant ones, for example, "On the basis of interviews . . . they divided the parents into four classes: demanding, over-anxious, unconcerned and normal", page 107), and on correlating and in some cases factor analysing the resultant scores. Yet an IQ figure is a summary of a person's performance on a wide variety of tasks, the component elements of which are unknown; correlation coefficients are liable to be treacherous even for the sophisticated (because, having obtained them, we may still not know what to do with them), and surveys of what has happened in a particular educational milieu must surely be of less interest to science than generalizations about what can be made to happen by systematic manipulation of the environment of individual children. I wish, therefore, that Professor Vernon had done more to encourage research workers in the educational field to move in this latter direction rather than content themselves with large-scale surveys of the traditional kind.

This, however, is basically a criticism of current educational research, not of Professor Vernon, who in fact has done an excellent job with the material at her disposal.

T. R. MILES

Medical Illustration

History of Medical Illustration from Antiquity to AD 1600. By Robert Herrlinger. Pp. 178. (Pitman: London, 1971.) £7.

THIS book was designed as the first volume of a two volume series to cover medical illustration from the earliest times to the present day. Regrettably because of the premature death of the author, only the first volume was completed and this covers the period from antiquity to AD 1600. The author, a distinguished medical historian, also received recognition as an art historian and as a result his illustrations are particularly notable for their artistry as well as their appositeness.

There is a masterly foreword by Dr Poynter, director of the Wellcome Institute of the History of Medicine. The book is profusely illustrated with nearly four hundred illustrations, many of which are beautifully reproduced in colour. Apart from the occasional American spelling the translation is good and lively. The text presents a scholarly interpretation and communication of historical research and there is a proper enquiry of the aims of medical illustration at particular periods. Herrlinger demonstrates by text and illustration that schematization is more typical of medical illustrations of the middle ages than naturalism, but everywhere the text shows the erudition and clarity of mind of the author. He regards the early cauterization pictures as examples of the use of indication lines and later points out that couches and beds supporting invalids are symbols of illness rather than actual representations. In like manner, he illuminates the symbolism behind the apparent crudity of many medical illustrations and reaches the conclusion that antique medical illustration included schematic, semi-schematic and naturalistic forms, in fact, all the categories of modern medical illustration. The early references to "squatting figures" are carried throughout the text and illustrations to make a continuous and recognizable record. Herrlinger explains this curious posture found in many early texts as derived from the need to make thighs and genitals accessible when the corpse is laid on the table for dissection and therefore feels it is more apt to use the term "mensa figures". There are a few spelling mistakes, for example "skillful" for skilful on page 49, but this is unusual and the text is on the whole beautifully printed.

This is a bibliophile's book not only for the quality of the printing and the binding but also because of the many references to title pages, frontispieces and other bibliophilic details to delight the heart of all who love books. It is somewhat disappointing therefore to see that the plates are not always set as conveniently in relation to the text as one would like. With such profuse illustration this can be difficult, but there seems little reason for setting plate 3, referred to on pages 15 and 16, at page 35, and plate 2 is referred to on page 41 and is set at page 18. Again plate 4 is referred to on page 19 and is set at page 36.

There is a list of locations of the manuscripts referred to in the text and an index devoted more to illustrators than illustrations. Herrlinger pays particular attention to Vesaelius; nearly thirty pages detail the development and influence of this prince of medical illustrators. Sixteenth century illustrations of surgery and instruments are treated less fully although there is a section on sixteenth century title pages.

These are relatively minor objections, however, to a fascinating history, although I doubt that many medical students would be prepared to spend this amount of money even on a beautifully produced, authoritative and profusely illustrated work of medical history and illustration. Certainly every medical library should have a copy.

EDWARD HITCHCOCK

Training and Testing

Animal Psychophysics: The Design and Conduct of Sensory Experiments. Edited by William C. Stebbins. Pp. xii+433. (Appleton–Century–Crofts: New York, December 1970.) $18.75.

THIS book is the outcome of a symposium held at the University of Michigan in 1969, during which the participants discussed their work on the behavioural analysis of sensory function in animals. The book contains eighteen articles, and the emphasis throughout is on the methods by which the animals were trained and tested. Such coherence as the book possesses thus comes from the techniques shared in common by the participants, and not from any of the problems that they are studying by means of these techniques. The book covers a wide range of sensory experiments on animals, including, for example, the detection of ultrasound by bats, of X-rays by rats and monkeys, and of sound by opossums and hedgehogs. In all cases, there are descriptions of how the stimuli were presented and the construction of the apparatus, and details of any idiosyncrasies that make that particular species difficult to work with.

The problems of obtaining accurate behavioural data on the sensory capacities of animals are important; among other things this is the only way in which the significance of physiological experiments on sensation can be assessed. The articles in this book show how well these problems have been solved in a variety of cases, and that it is possible to obtain psychophysical data from animals which are as accurate as those obtained from man. As a whole, however, the book has little unity. The various techniques of animal psychophysics that have been used do not seem to have very much in common with each other, and few general principles emerge. As in other fields of animal behaviour, each species presents different problems which need different solutions, and reading a paper on, for example, how to train and test monkeys helps only a little in designing an experiment for fish. A book this length can also include only an arbitrary and limited selection of the work in this field. The final impression is thus of a fairly random selection of contributions, often interesting in themselves, but only tenuously interrelated.

W. R. A. MUNTZ

Problems Solved

Applied Diffraction Theory. By F. H. Northover. (Modern Analytic and Computational Methods in Science and Mathematics: a Group of Monographs and Advanced Textbooks, No. 28.) Pp. 632. (Elsevier: New York, 1971.) £20.

THIS book provides a mathematical analysis of the solutions to problems involving time harmonic scalar waves and time harmonic electromagnetic waves. The author's selection of obstacles is restricted and the application of his mathematical results to problems in physics and engineering is not always emphasized. The choice of material is clearly personal and he does not attempt to review the literature relating to diffraction theory. He has, however, succeeded in providing the full mathematical analysis of problems that have interested him for more than twenty years. The mathematical topics are sophisticated and include separation of variables, eigenfunction expansions, special functions, contour integration, asymptotic methods and integral equations.

The early chapters are concerned principally with the propagation of electromagnetic waves around a perfectly conducting sphere embedded in a dielectric medium (a model for very high frequency propagation of radio waves around the Earth surrounded by a nonhomogeneous atmosphere). They reflect the author's interests before 1955. I was astonished and dismayed to read on page 114: "Since 1954 the writer's interest has moved from the subject of tropospheric propagation of radio waves to propagation through ionized gases and laboratory-type microwave diffraction problems. Therefore no attempt is made here to describe work in this field subsequent to 1955."

The next problem to be considered is diffraction of electromagnetic waves by a perfectly conducting cone of finite dimensions. The author published a solution in 1962 and a revised solution in 1965. On reviewing these papers, he found that certain aspects of his earlier solutions were open to criticism. In this book he presents a third investigation, paying special attention to the edge conditions, which were ignored in his earlier papers.

The third and last major topic concerns microwave lenses and the Fabry–Perot microwave interferometer, and is based on the Kirchhoff–Huygens diffraction theory. Fredholm integral equations are used extensively in the solution of some particular problems for interferometers consisting of two curved plates in the form of equal spherical caps.

The introduction to the ideas of diffraction theory in the first chapter is unsound. Insufficient attention is paid to the radiation condition at infinity. The reasoning behind the choice of the velocity potential of the diffracted wave in section 6.1 (the sphere diffraction problem—the acoustic case) is erroneous. There are statements of some possible boundary conditions, but no discussion of these boundary conditions and no mention of impedance boundary conditions. The necessity of imposing edge conditions in certain circumstances receives no attention, even though this is central to the investigation of the finite cone problem in the eighth and ninth chapters.

Also in the first chapter are exact solutions of some problems involving spherical obstacles. The author obtains some complete solutions using the separation of variables. His solutions by means of the infinite Legendre integral transform method are incomplete and purely formal. It is not clear why the integral transform method is worthy of consideration: the integral representing the solution of even the simplest problem looks intractable and attracts no comment. There is no discussion of the relative merits of the two methods of solution, although an oblique remark appears on page 622.

The third chapter, an account of the WKB approximation, would have been more widely usable (as an introduction) with some worked examples and exercises. The analysis is applied to the Airy equation, but the reader is expected to work through the previous twenty pages of technically difficult mathematics to appreciate the results stated for this particular case. There are three references, the most recent dated 1962. A slightly modified version of the chapter has been published by the author in the *Journal of Mathematical Physics* (**10**, 715; 1969).

The tenth chapter is devoted to some of the more important properties of linear integral equations. Some knowledge of standard Fredholm theory is presupposed. One reference (to Lovitt's book, first published in 1924) is provided in the sixty-seven pages of analysis written in theorem-proof style. In the author's subsequent use of integral equations (in connexion with the microwave problems) there is only one reference to this chapter. A shortened version of the chapter has appeared in the *Journal of Mathematical Analysis and Applications* (**29**, 305; 1970).

Much of the detailed analysis is in an appendix (of 142 pages). The mathematical supplement at the end of the book is in two parts, the first devoted to the method of steepest descents and the second devoted to the Watson transformation. This is a useful, well written section. The first part has been published in the *Journal of Mathematical Analysis and Applications* (**29**, 216; 1970). There are several references in the second part; however, in some cases only authors' names are given.

In my copy, there is a serious omission of the details of references 67–96, and there are two obvious mistakes (on page 18 $r^{-1}\ e^{ikr}$ appears instead of $r^{-1}\ e^{-ikr}$ and in section 6.1 of the sixteenth chapter Legendre appears instead of Laguerre).

To summarize, *Applied Diffraction Theory* is a detailed account of the mathematical solutions of a small selection of problems. It will interest a highly specialized readership.

D. PRYS THOMAS

CORRESPONDENCE

Skuas

SIR,—B. R. Johnston's "Skua Numbers and Conservation Problems at Cape Hallett, Antarctica" (*Nature*, **231**, 468; 1971) has been read with interest and understanding. However, the report requires further elaboration.

With reference to paragraph 3, it should be said that the resident penguins were moved from the area selected for establishing Hallett Station into other parts of the rookery. They were not killed or shipped from Cape Hallett as the verb "were removed" might suggest. This 1956 operation, supervised by Carl Eklund, USNC IGY, was carried out as humanely as possible, without losses, and in light of information then available on penguin behaviour.

With reference to paragraph 5, the remark that there was no significant loss of monel-metal bands is unclear. The statement on mean annual loss of breeding skuas, and on the fifty breeding birds lost between 1956 and 1967, requires substantiating data to indicate how these figures were derived. Similarly, figures for chicks fledged/females breeding may be based on end-of-the-season count and may result in greater actual breeding success than really exists.

For the benefit of those unfamiliar with skuas, it should be stated that the species is highly adaptive and quickly takes to feeding on food and other wastes available at all Antarctic camps; and that its willingness to take anything that can be swallowed has contributed to its mortality.

With reference to the last sentence, next to the last paragraph, Cape Hallett is not a Specially Protected Area. A very small part of Seabee Hook inland toward the cliffs has been designated as a Specially Protected Area for terrestrial botanical reasons.

In 1970–71, USARP biologists at Hallett Station began the restitution of the natural area; the work is continuing and will result in returning a large part of the land occupied by Hallett Station to the original inhabitants. The 1971–72 scientific work at Hallett Station includes a skua-banding programme by Dr John R. Baker, Iowa State University, in cooperation with Mr C. J. R. Robertson, Department of Internal Affairs, Wellington, New Zealand, for data which may help to establish the true status of the skua population at Cape Hallett, Antarctica.

Yours faithfully,

British Diary

Monday, November 1

Modern Food and Food Additives (6.30 p.m.) Dr D. W. Kent-Jones, Society of Chemical Industry, in association with the Industrial Division of the Chemical Society, in the Scientific Societies Lecture Theatre, 23 Savile Row, London W1.

Some Aspects of Drying Oils Technology (7 p.m.) Mr G. Hutchinson, Oil and Colour Chemists' Association, at the Queen's Hotel, George Street, Hull.

Tomorrow's World in Telecommunications (7 p.m.) Institution of Electrical Engineers, at the Royal Star Hotel, Maidstone, Kent.

Acrylic Resins (4 p.m.) Mr A. R. H. Tawn, Oil and Colour Chemists' Association, Thames Valley—Student Group, in the Main Lecture Theatre, Slough College, Slough.

Tuesday, November 2

Automatic Circuit Testing (7.30 p.m.) Mr D. Palmer, Institute of Measurement and Control, at the Peahen Hotel, St Albans.

Electrons in Solids (5.15 p.m.) Professor L. Pincherle, University of London, at Bedford College, Regent's Park, London NW1.

Migration and Interaction of Triplet Excitons (5.15 p.m.) Professor H. C. Wolf, Faraday Society, at the School of Chemistry, The University of Newcastle upon Tyne. (Bourke Lecture.)

The Excavations at Kalibangan (5.45 p.m.) Mr B. K. Thapar, University of London, at the Institute of Archaeology, 31/34 Gordon Square, London WC1.

Wednesday, November 3

Food Additives and Contaminants (3 p.m.) Society for Analytical Chemistry, at the Polytechnic of the South Bank, Borough Road, London SE1.

Henry Armstrong and School Science, 1880–1930 (1 p.m.) Dr W. H. Brock, Royal Institution, History of Science Discussion Group, at 21 Albemarle Street, London W1.

Migration and Interaction of Triplet Excitons (4 p.m.) Professor H. C. Wolf, Faraday Society, in the Department of Chemistry, The University of Manchester.

The Effectiveness of Modern Visual Communication Systems (6 p.m.) Mr B. Stapley, Institution of Electronic and Radio Engineers, at 9 Bedford Square, London WC1.

The Ionosphere and Radio Engineering (7 p.m.) Mr G. Millington, Institution of Electrical Engineers, at the University of Essex, Wivenhoe Park, Colchester, Essex.

Using Existing Resources Better—Planning for Future Growth (11 a.m. symposium) Institution of Chemical Engineers, jointly with the Society of Chemical Industry, at the University of Aston in Birmingham.

Thursday, November 4

Fermentation Pilot Plant Organization and Instrumentation (10.30 a.m., panel discussion) Society of Chemical Industry, Microbiology Group, at 14 Belgrave Square, London SW1.

Hazard Analysis — a Quantitative Approach to Safety (6.30 p.m.) Mr T. A. Kletz, Oil and Colour Chemists' Association, at the Royal Turks Head Hotel, Gret Street, Newcastle upon Tyne.

Migration and Interaction of Triplet Excitons (5 p.m.) Professor H. C. Wolf, Faraday Society, in the Department of Chemistry, The University of Sheffield.

Pressure Transmitter Design Parameters (7.30 p.m.) Mr C. H. Goode, Institute of Measurement and Control, at the Hotel Majestic, Park Place, Cheltenham.

Recent Developments in the Preservation of Foods (6.30 p.m.) Mr S. D. Holdsworth, Society of Chemical Industry, Food Group, at the School of Chemistry, University of Bristol.

Statistical Interpretations (7 p.m.) Mr M. Keegan, Society of Cosmetic Chemists of Great Britain, at the Royal Society of Arts, 6–8 John Adam Street, London WC2.

The Laws of Disorder. Part 1: Entropy; Part 2: The Second Law of Thermodynamics (1 p.m., ICI science films) Royal Institution, at 21 Albemarle Street, London W1.

The Pulsars (5.30 p.m.) Professor F. G. Smith, Institution of Electrical Engineers, Savoy Place, London WC2. (Appleton Lecture.)

Friday, November 5

Computer Controlled Frequency Response Measurements (5.30 p.m.) Mr A. J. Ley and Mr A. J. Martin, Institution of Electrical Engineers, at Savoy Place, London WC2.

Industrial Progress Associated with Analytical Research—Some Personal Experiences (5 p.m.) Mr A. F. Williams, Society for Analytical Chemistry, at the University of Strathclyde, Glasgow.

Making Sense of Music (9 p.m.) Professor H. C. Longuet-Higgins, FRS, Royal Institution, at 21 Albemarle Street, London W1.

Radiolysis of Nucleic Acids and Related Compounds (1 p.m.) Dr G. Scholes, Royal Institution, Photochemistry Discussion Group, at 21 Albemarle Street, London W1.

Saturday, November 6

Inca Architecture of Highland Peru (3.30 p.m.) Miss Anne Kendal, Inner London Education Authority, at the Horniman Museum, London Road, Forest Hill, London SE23.

Reports and Publications

not included in the monthly Books Supplement

Great Britain and Ireland

Science Research Council. The Work of the Rutherford Laboratory in 1970. Edited by J. R. Smith and F. M. Telling. Pp. 206. (Chilton, Didcot, Berks: Rutherford High Energy Laboratory, 1971.) [146

Papers and Proceedings of a Conference on Research into the Value of Time, held on 7th–8th May 1970, St. Christopher House, Southwark Street, London, SE1. Edited by N. W. Mansfield. (Time Research Note No. 16.) Pp. vi+131. (London: Highway Economics Unit, Department of the Environment, 1971.) *gratis* [146

PEP Broadsheet 527: Opting out of the NHS—a Review of the Private Sector of Medical Care. By Michael Lee. Pp. iv+28. (London: PEP, 1971.) 50p. [146

Productivity Measurement—a Symposium for the Seventies. Contributors: R. Allard, J. E. Keal, H. W. Mount, P. J. Samuel, G. R. Smith and A. R. Swannack. Pp. 50. (London: Institute of Personnel Management, 1971.) £1. [146

Xenobiotica, Vol. 1, No. 1 (January 1971). Published bi-monthly. Annual Subscription price (payable in advance) £15 postage paid. Subscribers in the USA., Canada and Mexico (air-freight) £16; $39.20 postage paid. Per part £3; $7.35 plus postage. Pp. 1–104. (London: Taylor and Francis, Ltd., 1971.) [146

J. J. Thompson Physical Laboratory, University of Reading. Research Report 1970–71. Pp. iv+61. (Reading: J. J. Thompson Physical Laboratory, 1971.) [146

Prospects in Health. Pp. 24. (London: Office of Health Economics 1971.) 15p. [176

Agricultural Research Council. Letcombe Laboratory—Annual Report 1970. Pp. ix+42. (Wantage: Letcombe Laboratory, 1971.) 50p. [186

A Guide to the Performance of the Standardized Rubella Hemagglutination-Inhibition Test. (Based on the publication of October 1970 by US Department of Health, Education and Welfare, Public Health Service, Health Services and Mental Health Administration, Center for Disease Control, Atlanta, Georgia, USA.) Pp. 43+9. Irvine, Ayrshire: Flow Laboratories, Ltd., Victoria Park, Heatherhouse Road, 1971.) 60p. [186

Potato Marketing Board: Sutton Bridge Experimental Station. Report No. 6: Storage Design and Equipment for Environmental Control in Potato Stores. Part 1: Storage Buildings. By O. J. H. Statham. Pp. ii+30. (London: Potato Marketing Board, 1971.) [216

Competition in Television. (An Address given by Huw Wheldon, Managing Director, BBC Television, at a Joint Meeting of the Faculty of Royal Designers for Industry and the Royal Society of Arts, 26 April 1971.) Pp. 15. (London: BBC, 1971.) [216

The Royal Observatory, Edinburgh. Publications—Vol. 7, No. 3: Photographic Photometry with Calcite Filter Calibration. (a) Inherent Error in the Method. By Peter W. J. L. Brand. (b) Its Use in the Near Infrared. By M. T. Brück. Pp. 35–45. Publications—Vol. 7, No. 4: Multicolour Photometry of the Stars in NGC 2264. By K. Nandy. Pp. 47–62. (Edinburgh: The Royal Observatory, 1971.) [216

Progress in Reaction Kinetics, Vol. 6, Part 1. Pp. 1–74. £1.60; $4.25. Progress in Reaction Kinetics, Vol. 6, Part 2. Pp. 75–141. £1.50; $4. (Oxford and New York: Pergamon Press, 1971.) [226

Daresbury Nuclear Physics Laboratory. Annual Report 1970. Pp. 134. (Daresbury, near Warrington: Science Research Council, Daresbury Nuclear Physics Laboratory, 1971.) [226

Guide to the Oxford Botanic Gardens. Pp. 42. (Oxford: Clarendon Press; London: Oxford University Press, 1971.) 40p net. [226

Field Studies Council. The Effects of Industry on the Environment. (Proceedings of a Symposium held at the Orielton Field Centre, Pembroke, South Wales, as part of a Contribution for European Conservation Year.) Pp. 58. (London: Field Studies Council, 9 Devereux Court, WC2, 1970.) [226

Courtaulds. Report and Accounts, 1970/1971. Pp. 25. (London: Courtaulds, Ltd., 1971.) [226

Philosophical Transactions of the Royal Society of London. B: Biological Sciences. Vol. 261, No. 839 (17 June 1971): A Discussion on Subcellular and Macromolecular Aspects of Synaptic Transmission. Organized by H. K. F. Blaschko and A. D. Smith. Pp. 273–437+plates 47–90. £7.75; $20. (London: The Royal Society, 1971.) [236

A Bulletin of Current Documentation, Vol. 1, No. 1, June 1971. Pp. 1–32. Published June, December and March. Annual subscription 75p for UK; £1; $2.50 elsewhere. (London: Association of Commonwealth Universities, 1971.) [236

Cement and Concrete Association. Report for the year 1970. Pp. 55. (London: Cement and Concrete Association, 1971.) [246

Other Countries

Académie Royale de Belgique. Classe des Sciences. Mémoires. Tome 29, Fasc. 5: Transformations Conformes er Quasi-Conformes des Variétés Riemanniennes Compactes (Démonstration de la Conjoncture de A. Lichnerowicz). Par Jacqueline Lelong-Ferrand. Pp. 44. (Bruxelles: Académia Royale de Belgique, 1971.) 100 francs. [116

The Use of Modules in College Biology Teaching. Edited by Joan G. Creager and Darrel L. Murray. Pp. viii+173. (Washington, DC: The Commission on Undergraduate Education in the Biological Sciences, 3900 Wisconsin Avenue, N.W., 1971.) *gratis*. [116

Académie Royale de Belgique. Annuaire pour 1971. Pp. 346+213. (Bruxelles: Académie Royale de Belgique, 1971.) [116

International Union for Conservation of Nature and Natural Resources. IUCN Publications, New Series, No. 20: IUCN Eleventh Technical Meeting—Papers and Proceedings, New Delhi, India, 25–28 November 1969. Vol. IV, Fifth Session, Commission on Education—Education Workshop. Environmental Conservation Education Among Populations of Rural and Woodland Areas. Pp. 156. (Morges, Switzerland: International Union for Conservation of Nature and Natural Resources, 1971.) [146

Académie Royale de Belgique. Classe des Sciences Mémoires, Tome 39, Fasc. 4: Chimie Organostannique—Structure, Mécanisme, Stéréochimie. Par J. Nasielski. Pp. 59. (Bruxelles: Académie Royale de Belgique, 1971.) 160 francs. [146

Commonwealth of Australia: Department of Supply. Defence Standards Laboratories Annual Report. 1969–1970. Pp. 62. (Maribyrnong, Victoria: Chief Superintendent, Defence Standards Laboratories, 1971.) [146

Les Sciences Occultes d'Après les Documents Littéraires Italiens du XVI^e^ Siècle. Par Viviana Paques. (Mémoires de l'Institut d'Ethnologie, No. VI.) Pp. 220. Le Bateau de Berck. Par F. Beaudouin. (Mémoires de l'Institut d'Ethnologie, V.) Pp. 210. (Paris: Université de Paris, Institut d'Ethnologie Musée de l'Homme, 1970 et 1971.) [146

Australia: CSIRO. Annual Report of the Division of Applied Chemistry 1969/1970. Pp. 41. (Melbourne: Commonwealth Scientific and Industrial Research Organization, 1971.) [166

World Health Organization. Technical Report Series, No. 463: WHO Expert Committee on Biological Standardization—Twenty-third Report. Pp. 94. (Geneva: WHO; London: HMSO, 1971.) 5 Swiss francs; 50p.; $1.75. [166

Proceedings of the North American Palaeontological Convention, Field Museum of Natural History, Chicago, September 5–7, 1969. Part G: Ultra Microplankton. 705–1010. Part H: Evolution of Higher Categories. Pp. 1011–1152. Part I: Extraordinary Fossils. Pp. 1153–1272. Part J: Reef Organisms Through Time. Pp. 1273–1482. Part K: Phosphate in Fossils. Pp. 1483–1562. Part L: Cretaceous Biogeography. Pp. 1563–1674. (Lawrence, Kansas: Allen Press, Inc. 1971.) [166

Canada: Department of Energy, Mines and Resources. Geological Survey of Canada. Paper 71–21: Massive Ice and Icy Sediments Throughout the Tuktoyaktuk Peninsula, Richards Island, and Nearby Areas, District of Mackenzie. By V. N. Rampton and J. Ross Mackay. Pp. v+16. Paper 70–45: Geology of Ennadai Lake Map-Area, District of Keewatin. By K. E. Eade. Pp. 19. $1.50. Paper 70–53: Geology, History and Potential of Vancouver Island Coal Deposits. By J. E. Muller and M. E. Atchison. Pp. viii+50. $2. Paper 70–60: Some Devonian Charophytes from Western Canada. By H. M. A. Rice. Pp. v+23. $1.50. Paper 70–67: Quaternary Geology Road Logs-Banff Area, Alberta. By Nathaniel W. Rutter. Pp. v+25. $0.75. (Ottawa: Information Canada, 1971.) [176

HOW TO BUY NATURE

Volumes start in January, March, May, July, September and November, but subscriptions may begin at any time.
The direct postal price per subscription is:-
12 MONTHS* (52 issues per title)

	Surface Mail UK and worldwide	Airfreight U.S.A. & Canada
Nature (Friday)	**£14**	**$48**
Nature+ Nature Physical Science	**£24**	**$83**
Nature+ Nature New Biology	**£24**	**$83**
All three editions	**£29.50**	**$108**
Annual Index	**£1**	**$3**

* Rates for shorter periods *pro rata* (minimum three months)
(Charge for delivery by air mail on application)
